INTRODUCTION

It is not an exaggeration to say that modern electric power systems are built on optimization models and solution techniques. Figure 1 shows a picture of the major optimization problems in power system operations with a timescale to indicate the horizon of the different types of decisions involved.

As a simple description, the long-term system planning studies the question of how much new generation and transmission capacity is needed and where in the power system they should be built in order to satisfy a projected future demand in a time horizon of 5–15 years or longer; the maintenance scheduling problem aims to optimally schedule the maintenance of generators, transformers, and other equipments so that the system operation will be disturbed as little as possible at a low cost, where the time horizon of decision is usually 1 year; the short-term operation problems determine daily or intraday generation schedules to match demand and satisfy various constraints.

All the major decision problems described earlier are built on two fundamental problems, the so-called unit commitment (UC) and economic dispatch based on optimal

power flow (OPF). In this article, we focus on these two problems and introduce their optimization models, important variations, and solution methods. We review both the basic formulations and the most recent advances in the field. In the remaining of the introduction, we give a brief overview of the basic structure of power systems with an introduction to common notations used in the literature. We then describe the UC and OPF problems.

A typical power system involves three major subsystems: generation, transmission network, and the distribution system. Figure 2 shows a simple illustration. The generation subsystem usually consists of industrial scale power plants, each of which normally has several generators, also called *generating units*. The voltage of the power produced by the generating units is stepped up by transformers to voltage levels at 138, 230 kV, or higher, before connecting to the transmission network. The high voltage levels help to reduce the thermal loss incurred during long distance transfer of power along transmission lines. The nodes of the transmission network, also called *buses* in the power system literature, represent physical points where the transmission lines connect to each other, and generators and/or loads are linked to the network. Transmission network is usually sparse and meshed. Before the power is served to the load, voltage is again stepped down to low levels of a few kilo volts and ultimately to 120 or 240 V in North America. This low voltage network is called the *distribution system*, which directly connects to the end users of electricity.

The generation scheduling problem considered in this article mainly deals with the high voltage transmission network, although with the increase of distributed generators, the distribution system is changing from a largely consumer network to a hybrid of power consumers and suppliers. The models we present in this article can be extended to the distribution system as well.

Figure 1. Major problems in power systems operation. The time arrow points to the start of real-time operation. The locations of the problems on the time arrow indicate their relative distance to the real-time operation. The typical decision horizon of each problem is given under each problem.

Figure 3 shows a simple example of a power system, which has 14 buses, 20 transmission lines, 5 generators, and 11 loads. Transformers, breakers, and other equipments are ignored. Denote the set of buses in the system as $\mathcal{N} = \{1, 2, \dots, 13\}$, and the subset of buses connected to generators as $\mathcal{G} = \{1, 2, 3, 6, 8\}$. Denote the set of transmission lines as $\mathcal{L} = \{(1, 2), (1, 5), (2, 5), \dots, (13, 14)\}$, where each transmission line is specified by its two end buses. Each transmission line (i, j) is characterized by its electrical properties, such as the conductance g_{ij} and the susceptance b_{ij} .

Each generation unit can be either turned on to produce electricity or turned off. When the generation unit is turned on, it is called *committed*; when it is turned off, it is called *decommitted*. The on/off state of a generator is called its *commitment status*. The unit commitment problem determines the commitment status and generation output of each generator to satisfy electricity demand over a time horizon of a day or a few days. There are various constraints in the UC problem. For example, the minimum up (down) time constraints require the generators remain in the on (off) state for a minimum amount of time once they are turned on (off); the ramping constraints require that the change in generation output between two consecutive time periods of a generator cannot exceed a limit; there are also constraints on the maximum and minimum generation output levels that each generator can achieve, and transmission network constraints that involve power flow equations and power flow limits on transmission lines; there are also constraints on the voltage limits on buses. The commitment statuses of generators are modeled as

binary decision variables in the UC problem, and the generation output levels and voltage levels are modeled as continuous variables. As we will discuss in details later, the power flow equations and network constraints involve nonlinear nonconvex functions of the continuous variables. Therefore, the unit commitment is a mixed-integer nonlinear nonconvex optimization problem. In practice, linear approximations of the nonconvex power flow constraints are widely used, which simplifies UC to a mixed-integer linear optimization problem.

The UC problem is solved a day before the real-time operation in order to accommodate long starting and shutting down times of generators. Once the UC problem is solved, the commitment decision for the next day is fixed. When real-time operation starts, the system operator dispatches the committed generators to meet realized demand at a minimum total generation cost. This procedure is called *economic dispatch*. The underlying optimization problem is called *OPF*, which has a similar set of constraints as in the UC problem, except that it only involves continuous decision variables, that is, generation output and voltages, and very often only has one decision period (therefore, the ramping constraints are not considered in this case). The OPF problem is solved every 5–15 min.

Owing to the nonlinear and nonconvex nature of the UC and OPF, it is still a challenge to obtain fast, robust solutions to these problems in large-scale power systems. New challenges are emerging too. For example, unconventional generators such as wind and solar power are intrinsically stochastic; how to deal with such uncertainties poses

Figure 2. The basic structure of a typical electric power system consists of the generation, the transmission network, and the distribution system. *Source:* FERC [1].

challenges for large-scale integration of variable generation resources into the power grid. In this article, we introduce fundamental models and discuss some of the most recent advances in meeting these challenges.

The rest of this article is organized as follows. The section titled “Optimal Power Flow Problem” introduces power flow equations and OPF models. The section titled “Global Optimization Methods for AC OPF” introduces global optimization methods to exactly solve the OPF problem. Two lower bounding techniques, the Lagrangian relaxation and the semidefinite relaxation methods, are discussed in detail. The section titled “Distributed Algorithms for AC OPF” motivates decentralized optimization schemes for solving large-scale OPF problems and reviews the literature. The section titled “Security-Constrained Optimal Power Flow Problem” reviews the important problem of security-constrained OPF and solution methods. The UC and its optimization formulation are introduced in the section titled “Security-Constrained Unit Commitment Problem.” The recent development of the adaptive robust UC model is reviewed in the section titled “Adaptive Robust Optimization for SCUC under Uncertainty.”

OPTIMAL POWER FLOW PROBLEM

As introduced in the previous section, OPF is a nonconvex, nonlinear optimization problem. The most defining constraints of the problem are the ones involving alternating current (AC) power flow equations, which describe the relationship between generator power output, bus voltages, and power flows on the transmission lines. In this section, we first introduce two equivalent AC OPF formulations with AC power flow equations. Then, we discuss a linear approximation of the AC power flow equations, which leads to the so-called DC OPF problem.

AC OPF Models

In the AC model, voltage and power are expressed as complex numbers. In the rectangular coordinates, the voltage V_i at a bus

$i \in \mathcal{N}$ can be expressed as

$$V_i = e_i + jf_i,$$

where $j = \sqrt{-1}$ is the imaginary unit and e_i and f_i are the real and imaginary parts of the complex voltage, respectively. Similarly, the power injected into a bus i can be also decomposed into the real part, the active power P_i , the imaginary part, and the reactive power Q_i . In power flow equations, we are concerned with the *net* power injection at a bus i , which is the difference between the power injected from the generator at bus i expressed as $p_i^g + jq_i^g$ and the power consumed by the load $p_i^d + jq_i^d$; therefore, $P_i = p_i^g - p_i^d$, and $Q_i = q_i^g - q_i^d$.

The AC OPF problem of minimizing the total generation cost is given as

$$\min_{e, f, p^g, q^g} c(p^g) = \sum_{i \in \mathcal{G}} (c_{i0}(p_i^g)^2 + c_{i1}p_i^g + c_{i2}) \quad (1a)$$

$$\text{s.t. } p_i^g - p_i^d = \sum_{j \in \mathcal{N}} (G_{ij}(e_i e_j + f_i f_j) - B_{ij}(e_i f_j - e_j f_i)), \quad \forall i \in \mathcal{N} \quad (1b)$$

$$q_i^g - q_i^d = \sum_{j \in \mathcal{N}} (-G_{ij}(e_i f_j - e_j f_i) - B_{ij}(e_i e_j + f_i f_j)), \quad \forall i \in \mathcal{N} \quad (1c)$$

$$| -G_{ij}(e_i^2 + f_i^2 - e_i e_j - f_i f_j) | - B_{ij}(e_i f_j - e_j f_i) \leq p_{ij}^{\max}, \quad \forall (i, j) \in \mathcal{L} \quad (1d)$$

$$(v_i^{\min})^2 \leq e_i^2 + f_i^2 \leq (v_i^{\max})^2, \quad \forall i \in \mathcal{N} \quad (1e)$$

$$p_i^{\min} \leq p_i^g \leq p_i^{\max}, \quad \forall i \in \mathcal{G} \quad (1f)$$

$$q_i^{\min} \leq q_i^g \leq q_i^{\max}, \quad \forall i \in \mathcal{G}, \quad (1g)$$

where Equations (1b and 1c) are the AC power flow equations; G_{ij} and B_{ij} are defined as

$$G_{ij} = \begin{cases} -g_{ij} & \text{if } i \neq j \\ g_{ii} + \sum_{k \neq i} g_{ik} & \text{if } i = j \end{cases}$$

$$B_{ij} = \begin{cases} -b_{ij} & \text{if } i \neq j \\ b_{ii} + \sum_{k \neq i} b_{ik} & \text{if } i = j \end{cases}$$

As mentioned earlier, g_{ij} and b_{ij} are the conductance and susceptance of the transmission line (i, j) , respectively, and g_{ii} and

Figure 3. An example diagram of a power system with 14 buses; 20 transmission lines; 5 generators (the circle symbols) at buses 1, 2, 3, 6, and 8; and 11 loads (the arrows pointing out from buses) [2].

b_{ii} are the conductance and susceptance from the node i to the ground; constraint (Eq. 1d) ensures that the active power flow on each transmission line is within its limit $p_{ij}^{\max}$; constraint (Eq. 1e) imposes upper and lower bounds, $v_i^{\max}$ and $v_i^{\min}$, on the voltage magnitude at each bus; constraints (Eqs. 1f and 1g) set the upper and lower bounds on the active and reactive power output of generators, $p_i^{\max}, p_i^{\min}, q_i^{\max}, q_i^{\min}$, respectively. The objective (1a) models the generation cost as a quadratic function of the active power output of the generators, which is a common practice in the power industry. Sometimes, other objective functions such as the total power loss in transmission lines or other constraints such as apparent power flow limits are considered.

The above-mentioned AC OPF formulation (Eq. 1) is a nonconvex quadratic optimization model. Another equivalent formulation can be derived by expressing the complex bus voltages in the polar coordinates as

$$V_i = v_i e^{j\theta_i} = v_i (\cos \theta_i + j \sin \theta_i),$$

where v_i is the magnitude and θ_i is the phase angle of the complex voltage. In this representation, the AC OPF problem can be written as

$$\begin{aligned} \min_{v, \theta, p^g, q^g} \quad & \sum_{i \in \mathcal{G}} (c_{i0} (p_i^g)^2 + c_{i1} p_i^g + c_{i2}) \\ \text{s.t.} \quad & p_i^g - p_i^d = \sum_{j \in \mathcal{N}} G_{ij} v_i v_j \cos(\theta_i - \theta_j) \\ & + B_{ij} v_i v_j \sin(\theta_i - \theta_j), \quad i \in \mathcal{N} \quad (2a) \end{aligned}$$

$$\begin{aligned} q_i^g - q_i^d = \sum_{j \in \mathcal{N}} G_{ij} v_i v_j \sin(\theta_i - \theta_j) \\ - B_{ij} v_i v_j \cos(\theta_i - \theta_j), \quad i \in \mathcal{N} \quad (2b) \end{aligned}$$

$$\begin{aligned} & | -G_{ij} (v_i^2 - v_i v_j \cos(\theta_i - \theta_j)) \\ & + B_{ij} v_i v_j \sin(\theta_i - \theta_j) | \\ & \leq p_{ij}^{\max}, \forall (i, j) \in \mathcal{L} \quad (2c) \end{aligned}$$

$$v_i^{\min} \leq v_i \leq v_i^{\max}, \quad \forall i \in \mathcal{N} \quad (2d)$$

(1f), (1g)

The rectangular formulation (1) and polar formulation (2) are equivalent in the way that an optimal solution of one formulation can be easily transformed to an optimal solution of the other. From the optimization modeling and computation perspective, one advantage of the polar formulation (2) is that the voltage magnitude constraints (Eq. 2d) are simple linear bounding constraints, whereas in the rectangular representation model (Eq. 1e), the voltage magnitude constraints (Eq. 1e) are nonconvex quadratic constraints. Furthermore, sometimes the system operation requires the voltage magnitude at certain buses be fixed, which leads to a reduction of number of variables in the polar formulation, but an increase in the number of quadratic equality constraints in the rectangular formulation. However, there are also compelling reasons to use the rectangular formulation. First, Equation (1) is a quadratic optimization problem, whose Hessian matrix is constant; this is convenient for the application of interior-point methods. Second, the elimination of trigonometric functions also speeds up function evaluations. Third, the rectangular model is commonly used in practice because they facilitate the use of certain fast-decoupled solution methods for solving the power flow problem [3].

DC OPF Model

The AC OPF model involves nonconvex quadratic or trigonometric functions. It is still a computational challenge to solve large-scale AC OPF problems in a fast and robust way. In practice, the linear approximation model with linearized power flow equations has been widely used. It is usually called the *DC OPF model*, although it should not be confused with direct current. The DC power flow equations are obtained from the polar representation of power flow equations (Eqs 2a and 2b). The basic steps of the approximation are outlined here:

- We assume $G_{ij} = 0$ for all $(i, j) \in \mathcal{L}$, because the line resistance is usually very small.
- Under normal operating conditions, the voltage angle difference between two

connected buses is usually small, that is, $(\theta_i - \theta_j) \approx 0$, which implies $\sin(\theta_i - \theta_j) \approx (\theta_i - \theta_j)$ and $\cos(\theta_i - \theta_j) \approx 1$.

- Under normal operating conditions, the magnitudes of bus voltages are also close to each other, that is, if we normalize the bus voltages with respect to a common voltage unit, then the product of two bus voltages is again close to the unit 1.

Combining these three steps, the DC OPF model is given as:

$$\begin{aligned} & \min_{\mathbf{p}^g, \theta} \sum_{i \in \mathcal{G}} (c_{i2}(p_i^g)^2 + c_{i1}p_i^g + c_{i0}) \\ \text{s.t. } & \sum_{j \in \mathcal{N}} B_{ij}(\theta_i - \theta_j) = p_i^g - p_i^d, \quad \forall i \in \mathcal{N} \quad (3a) \\ & B_{ij}(\theta_i - \theta_j) \leq p_{ij}^{\max}, \quad \forall (i, j) \in \mathcal{L} \\ & p_i^{\min} \leq p_i^g \leq p_i^{\max}, \quad i \in \mathcal{G}, \quad (3b) \end{aligned}$$

where the AC power flow equations (Eqs 2a and 2b) are approximated by the linear equalities (Eq. 3a) and the power flow constraints (Eq. 2c) are approximated by linear inequalities (Eq. 3b).

Under normal operating conditions, the DC OPF model gives quite accurate approximation for the active power output of generators, and the solution methods for the convex DC OPF problem (Eq. 3) are much faster and robust. However, it does not account for reactive powers, and the approximation can lead to significant errors for stressed systems.

In the early 1960s, Carpentier originally introduced the AC OPF problem and made the first attempt to solve it [4]. Since then, many solution approaches have been studied, including successive linear/quadratic programming [5], trust-region-based methods [6], Lagrangian–Newton methods [7], and interior-point methods [8]. See [3] for a recent review. These approaches usually require a centralized implementation and aim to find a local solution satisfying first-order optimality conditions. Global optimization algorithms and distributed algorithms are also proposed in the literature. In this article, we focus on these two types of algorithms.

GLOBAL OPTIMIZATION METHODS FOR AC OPF

In this section, we introduce exact methods to solve the AC OPF problem (1) to global optimality. First, we discuss two methods to obtain lower bounds on the global optimal solution, namely the Lagrangian relaxation in the section titled “Lagrangian Relaxation” and the semidefinite programming relaxation in the section titled “Semidefinite Programming Relaxation.” Then, the global optimization methods for AC OPF, when these relaxations have a nonzero duality gap, are introduced in the section titled “Branch-and-Bound Algorithms.”

Lagrangian Relaxation

To present the Lagrangian relaxation method, we first formulate the Lagrangian dual function and the corresponding Lagrangian dual problem. Then, we show an efficient decomposition method for evaluating the dual function. This is essential in making the Lagrangian relaxation method practically useful.

The Lagrangian dual problem of the primal AC OPF (Eq. 1) is formed by dualizing the quadratic constraints (Eqs 1b–1e), while retaining simple bounding constraints (1f and 1g). The Lagrangian function is defined as

$$\begin{aligned} L(\mathbf{e}, \mathbf{f}, \mathbf{p}^g, \mathbf{q}^g, \lambda, \beta, \mu, \gamma, \eta) = & c(\mathbf{p}^g) + \sum_{i \in \mathcal{N}} \left(\lambda_i \left(\sum_{j \in \mathcal{N}} (e_i(G_{ij}e_j - B_{ij}f_j) + f_i(G_{ij}f_j + B_{ij}e_j)) + p_i^d \right) \right. \\ & + \beta_i \left(\sum_{j \in \mathcal{N}} (f_i(G_{ij}e_j - B_{ij}f_j) - e_i(G_{ij}f_j + B_{ij}e_j)) + q_i^d \right) + \sum_{(i,j) \in \mathcal{L}} \mu_{ij}(-(e_i^2 + f_i^2)G_{ij} \\ & + (e_ie_j + f_if_j)G_{ij} - (e_if_j - e_jf_i)B_{ij}) + \sum_{i \in \mathcal{N}} (\eta_i - \gamma_i)(e_i^2 + f_i^2) - \sum_{i \in \mathcal{G}} (\lambda_i p_i^g + \beta_i q_i^g). \end{aligned}$$

$$\begin{aligned} \min_{\mathbf{e}, \mathbf{f}, \mathbf{p}^g, \mathbf{q}^g} \quad & L(\mathbf{e}, \mathbf{f}, \mathbf{p}^g, \mathbf{q}^g, \lambda, \beta, \mu, \gamma, \eta) \\ - \sum_{(i,j) \in \mathcal{L}} \mu_{ij} p_{ij}^{\max} + \sum_{i \in \mathcal{N}} (\gamma_i (v_i^{\min})^2 - \eta_i (v_i^{\max})^2) \end{aligned} \quad (4a)$$

$$\text{s.t. } (1f), (1g) \quad (4b)$$

$$\sum_{i \in \mathcal{N}} (v_i^{\min})^2 \leq \sum_{i \in \mathcal{N}} (e_i^2 + f_i^2) \leq \sum_{i \in \mathcal{N}} (v_i^{\max})^2. \quad (4c)$$

Notice that the sphere constraints (Eq. 4c) are redundant because of the bounding constraints (Eq. 1e) on nodal voltages. However, the inclusion of Equation (4c) will help solve Equation (4) analytically, as shown in the following discussion.

It is known that for any feasible value of the Lagrange multipliers $\{(\lambda, \beta, \mu, \gamma, \eta) : \mu \geq 0, \gamma \geq 0, \eta \geq 0\}$, the value of the dual objective function, $g(\lambda, \beta, \mu, \gamma, \eta)$, provides a lower bound on the global optimal objective function value of Equation (1). Therefore, to

obtain the best lower bound for all feasible multipliers, we need to solve the following Lagrangian dual problem:

$$\begin{aligned} \max_{\lambda, \beta, \mu, \gamma, \eta} \quad & g(\lambda, \beta, \mu, \gamma, \eta) \\ \text{s.t. } \quad & \mu \geq 0, \\ & \gamma \geq 0, \eta \geq 0. \end{aligned} \quad (5)$$

This is a concave maximization problem, so an optimal solution can be obtained by convex optimization techniques. However, the practical use of the Lagrangian duality method greatly depends on how efficiently the function value and a subgradient of $g(\lambda, \beta, \mu, \gamma, \eta)$ can be evaluated, which is related to how efficiently the inner nonconvex problem (4) can be solved. It is shown in the following equations that Equation (4) is tractable because of its special structure. In particular, problem (4) can be decomposed into two subproblems: a convex separable quadratic optimization problem with simple box constraints

$$\begin{aligned}
\min_{\mathbf{p}^g, \mathbf{q}^g} \quad & c(\mathbf{p}^g) - \sum_{i \in \mathcal{G}} (\lambda_i p_i^g + \beta_i q_i^g) \\
\text{s.t.} \quad & p_i^{\min} \leq p_i^g \leq p_i^{\max}, \quad q_i^{\min} \leq q_i^g \leq q_i^{\max}, \\
& \forall i \in \mathcal{G}
\end{aligned} \tag{6}$$

and a nonconvex quadratic optimization problem with two sphere constraints

$$\begin{aligned}
\min_{\mathbf{x}} \quad & \mathbf{x}^T \mathbf{A}(\lambda, \beta, \mu, \gamma, \eta) \mathbf{x} \\
\text{s.t.} \quad & \sum_{i \in \mathcal{N}} (v_i^{\min})^2 \leq \mathbf{x}^T \mathbf{x} \leq \sum_{i \in \mathcal{N}} (v_i^{\max})^2, \tag{7}
\end{aligned}$$

where $\mathbf{x} = [\mathbf{e}^T \mathbf{f}^T]^T$ and the matrix $\mathbf{A}(\lambda, \beta, \mu, \gamma, \eta)$ are given as

$$\begin{aligned}
\mathbf{A}(\lambda, \beta, \mu, \gamma, \eta) = & \left(\begin{bmatrix} \lambda_1 \mathbf{G}_1; -\beta_1 \mathbf{B}_1; \\ \vdots \\ \lambda_{|\mathcal{M}|} \mathbf{G}_{|\mathcal{M}|}; -\beta_{|\mathcal{M}|} \mathbf{B}_{|\mathcal{M}|}; \\ \beta_1 \mathbf{G}_1; +\lambda_1 \mathbf{B}_1; \\ \vdots \\ \beta_{|\mathcal{M}|} \mathbf{G}_{|\mathcal{M}|}; +\lambda_{|\mathcal{M}|} \mathbf{B}_{|\mathcal{M}|}; \end{bmatrix} \begin{bmatrix} -\beta_1 \mathbf{G}_1; -\lambda_1 \mathbf{B}_1; \\ \vdots \\ -\beta_{|\mathcal{M}|} \mathbf{G}_{|\mathcal{M}|}; -\lambda_{|\mathcal{M}|} \mathbf{B}_{|\mathcal{M}|}; \\ \lambda_1 \mathbf{G}_1; -\beta_1 \mathbf{B}_1; \\ \vdots \\ \lambda_{|\mathcal{M}|} \mathbf{G}_{|\mathcal{M}|}; -\beta_{|\mathcal{M}|} \mathbf{B}_{|\mathcal{M}|}; \end{bmatrix} \right) + \begin{pmatrix} \mathbf{G}(\mu), & -\mu \circ \mathbf{B} \\ \mu \circ \mathbf{B}, & \mathbf{G}(\mu) \end{pmatrix} + \text{diag}([\eta - \gamma; \eta - \gamma]),
\end{aligned}$$

where $\mathbf{G}_i$ and $\mathbf{B}_i$ are the i th rows of matrices $\mathbf{G}$ and $\mathbf{B}$, respectively; $\text{diag}(\mathbf{x})$ is a diagonal matrix with $\mathbf{x}$ on the diagonal; “ $\circ$ ” denotes the componentwise product; and $\mathbf{G}(\mu)$ has the ij th component as $\mu_{ij} G_{ij}$ for off-diagonal element and $\sum_{j \neq i} -\mu_{ij} G_{ij}$ for the i th diagonal element.

Owing to the special structure, a global optimal solution $\mathbf{x}^*$ of Equation (7) has the following closed form

$$\mathbf{x}^* = \begin{cases} \mathbf{v} \sqrt{\frac{\sum_{i \in \mathcal{N}} (v_i^{\max})^2}{\|\mathbf{v}\|}}, & \text{if } \lambda_{\min} < 0 \\ \mathbf{v} \sqrt{\frac{\sum_{i \in \mathcal{N}} (v_i^{\min})^2}{\|\mathbf{v}\|}}, & \text{otherwise,} \end{cases}$$

where $\mathbf{v}$ is the eigenvector associated with the smallest eigenvalue $\lambda_{\min}$ of the matrix $\mathbf{A} + \mathbf{A}^T$. Therefore, solving Equation (7) amounts to computing the extreme eigenvector of the matrix. The conductance $\mathbf{G}$ and susceptance $\mathbf{B}$ matrices of real-world power systems are often sparse with graph density less than 0.1, thus $\mathbf{A} + \mathbf{A}^T$ is also sparse. Hence, sparse techniques can be applied to further reduce the computational burden.

The objective function value and a subgradient of $g(\lambda, \beta, \mu, \gamma, \eta)$ can be computed from the solutions of Equations (6 and 7). Thus, the dual problem (5) as a convex non-differentiable optimization problem can be

efficiently solved by a subgradient projection method, which gives a lower bound on the global optimal function value. One can use the optimal solution found in the previous period as a warm start for the next problem. Furthermore, it is observed that the Lagrangian multiplier from the primal problem is often a good initial guess for the dual problem [9].

Semidefinite Programming Relaxation

In this section, we briefly discuss another relaxation technique to find a lower bound for the AC OPF problem, which is first proposed in Ref. 10. The observation is that as the AC OPF in the rectangular coordinate is a quadratically constrained quadratic program (QCQP), and it is well known that any QCQP can be relaxed to a semidefinite programming (SDP) problem, then the AC OPF problem can also be relaxed to an SDP problem, which is convex and thus solvable in polynomial time by interior-point methods.

The basic procedure of formulating the SDP relaxation can be described as follows. First, the AC OPF problem, as a nonconvex QCQP problem, can be reformulated as an equivalent optimization problem involving matrix variables, where the matrix variables are constrained to be positive semidefinite and have rank one. Besides the rank constraint, which is a nonconvex constraint and

difficult to deal with, all other constraints of the reformulated optimization problem are linear in the matrix variables. Therefore, by removing the rank constraint, we come to a linear SDP problem, given in the following equation

$$\min_{W, \alpha} \sum_{i \in \mathcal{G}} \alpha_i \quad (8a)$$

$$\text{s.t.} \quad \begin{cases} c_{i1}(\text{trace } \mathbf{Y}_i W + p_i^d) + c_{i2} - \alpha_i \\ \sqrt{c_{i0}}(\text{trace } \mathbf{Y}_i W + p_i^d) \\ \sqrt{c_{i0}}(\text{trace } \mathbf{Y}_i W + p_i^d) \\ -1 \end{cases} \pi 0, \quad \forall i \in \mathcal{G} \quad (8b)$$

$$p_i^{\min} - p_i^d \leq \text{trace } \mathbf{Y}_i W \leq p_i^{\max} - p_i^d, \quad \forall i \in \mathcal{N} \quad (8c)$$

$$q_i^{\min} - q_i^d \leq \text{trace } \bar{\mathbf{Y}}_i W \leq q_i^{\max} - q_i^d, \quad \forall i \in \mathcal{N} \quad (8d)$$

$$\text{trace } \mathbf{Y}_{ij} W \leq p_{ij}^{\max}, \quad \forall (i, j) \in \mathcal{L} \quad (8e)$$

$$(v_i^{\min})^2 \leq \text{trace } \mathbf{M}_i W \leq (v_i^{\max})^2, \quad \forall i \in \mathcal{N} \quad (8f)$$

$$W \geq 0. \quad (8g)$$

The parameters $\mathbf{Y}_i$, $\bar{\mathbf{Y}}_i$, and $\mathbf{Y}_{ij}$ are matrices formed from conductance and susceptance matrices of the electric network. $\mathbf{M}_i$ is a square matrix of size $2|\mathcal{N}|$ with a 1 in the i th and $(i + |\mathcal{N}|)$ th diagonal entries and 0's elsewhere [10], and W is the relaxation of matrix $(\mathbf{e}^T; \mathbf{f}^T)(\mathbf{e}^T; \mathbf{f}^T)^T$.

The dual problem of the above-mentioned SDP is again an SDP, and there is no duality gap between the two. Furthermore, solving the dual SDP has certain advantages over solving the primal problem (8). For example, the number of decision variables in the dual SDP is essentially linear with respect to the number of buses $|\mathcal{N}|$, as opposed to being quadratic in Equation (8). In addition, it is easier to work with the dual SDP to detect whether the solution of the relaxation problem recovers a global optimal solution [10].

Branch-and-Bound Algorithms

Numerical experiments on IEEE test systems show that the Lagrangian relaxation and the SDP relaxation work surprisingly well

to recover the global optimization solutions for the AC OPF problems [9, 10]. However, in general, there is no theoretical guarantee that these relaxation methods find a global optimum. Indeed, it has been shown that the relaxations can give a strictly lower bound to the global optimal objective value on some simple electric networks [11]. This raises the need to develop algorithms that guarantee to find a global optimum for the AC OPF problems. It is still a relatively less explored field. The recent work in Refs 9 and 11 proposes such algorithms based on the branch-and-bound principle. We note that the SDP and the Lagrangian dual relaxations give the same lower bounds, but they could differ in computational performance.

In the following, we briefly describe the general branching and pruning procedures of these algorithms. First, the branch-and-bound algorithm starts from a root node that corresponds to a set of the decision variables that contains the feasible region of the original AC OPF problem (1), denoted as Ω . For example, the following set would suffice to be the root node

$$\begin{aligned} \mathcal{B}_0 = \{(\mathbf{p}^g, \mathbf{q}^g, \mathbf{e}, \mathbf{f}) : \mathbf{p}^{\min} \leq \mathbf{p}^g \leq \mathbf{p}^{\max}, \\ \mathbf{q}^{\min} \leq \mathbf{q}^g \leq \mathbf{q}^{\max}, (v_i^{\min})^2 \leq e_i^2 + f_i^2 \leq (v_i^{\max})^2, \\ \forall i \in \mathcal{N}\}. \end{aligned}$$

Any subsequent node in the search tree corresponds to a subset of $\mathcal{B}_0$, generated by branching from its parent node. The branching corresponds to a partition of the search set associated with the parent node, which can be implemented by either a rectangular bisection over the upper and lower bounds on the real and reactive power, $\mathbf{p}^g$ and $\mathbf{q}^g$ as proposed in Ref. 9, or a radial bisection over the voltage magnitude as proposed in Ref. 11.

A search node is called *active*, if it has not been pruned. At an active node of iteration k , denoted as $\mathcal{B}_k$, the algorithm solves the Lagrangian or SDP relaxation of a modified AC OPF problem with a feasible region defined as $\Omega \cap \mathcal{B}_k$. This feasible region can be easily constructed from the original AC OPF by appending the constraints in $\mathcal{B}_k$, which are bounds on $\mathbf{p}^g, \mathbf{q}^g$, and voltage magnitudes. Recall that such bounding constraints

are amiable for the decomposition described in the section titled “Lagrangian Relaxation” for the Lagrangian relaxation. Furthermore, both the rectangular partition and the radial partition preserve this bounding structure of the search sets. Therefore, the Lagrangian relaxation can be efficiently solved, and the SDP relaxation can be formulated and solved just as for the original AC OPF.

The obtained lower bound is compared to the smallest objective function value of the incumbent solution, which is based on the best feasible solution found so far in the branch-and-bound process and also provides an upper bound on the global optimum. The current search node is pruned if the obtained lower bound is higher than the best objective value of the incumbent solution or the lower bound is $+\infty$, which means the modified AC OPF is infeasible; otherwise, the incumbent is replaced by the obtained lower bound and the current node remains active.

The feasible region for $\mathbf{p}^g$ shrinks at every step of the branch-and-bound process; therefore, a nested sequence of bisections shrinks to a singleton. Because the objective function is a function of only $\mathbf{p}^g$, for any sequence of infinitely decreasing partition elements, the upper and lower bounds converge in the limit. Thus, the bounding scheme is consistent. The selection rule for choosing partition elements also improves bounds. Hence, the branch-and-bound algorithm is convergent [9].

DISTRIBUTED ALGORITHMS FOR AC OPF

Previous sections introduce models and solution methods for the AC OPF problems, which require a central control entity to gather system-wide information and to implement the solution algorithms. This centralized operation scheme is widely used in today’s power industry.

However, in some situations, decentralized decision-making is more appealing or even necessary. For instance, in a large power system involving multiple interconnected control areas, global information pooling and sharing may be limited by institutional arrangements. Owing to this, a centralized OPF algorithm for the entire interconnection may not be properly implementable. Instead,

a decentralized operation scheme can be utilized to achieve a coordinated dispatch, which often improves the economics of the entire system comparing to individual dispatch without coordination.

A decentralized operation scheme usually relies on an iterative process of computation and communication. Within an iteration, each subsystem operator solves a modified OPF problem for its own control area, which involves parameters that will be updated from the solutions of its adjacent subsystems. The parameter update is accomplished by communication between subsystems. Baldick and his colleagues in a series of papers first demonstrated the viability of the decentralized scheme for coordination of subcontrol areas in a large power system [12, 13]. Since then, several papers have contributed to the topic. In the following, we summarize the existing approaches based on the OPF models, decomposition methods, and algorithmic frameworks.

- **OPF Models.** Both AC and DC OPF problems have been studied. In particular, [12–15] have proposed distributed algorithms for AC OPF problems, whereas [16, 17] have proposed for DC OPF problems. In [17], the authors use a nonlinear DC model to account for network losses.
- **Decomposition Methods.** A large power system is usually divided into subcontrol regions interconnected by tie lines. The couplings between subsystems arise from constraints such as power flow balance equations and thermal limits on transmission lines. In order to apply a distributed algorithm, the coupling between subsystems need to be broken down. A common idea behind the proposed decomposition methods is to introduce redundant variables in the overlapping regions between subsystems. These redundant variables can be power injections and voltages on fictitious buses introduced on tie lines [12, 13, 15, 17]; or, redundant power flow variables on tie lines [14, 16].

• **Algorithmic Framework.** After redundant variables are introduced, the centralized OPF model is decomposed into subproblems. A common approach is to relax coupling constraints using Lagrangian relaxation or some of its variants. In particular, the existing proposals can be divided into two groups. The first group uses the exact framework of Lagrangian or augmented Lagrangian relaxation, where the coupling constraints are relaxed by introducing Lagrange multipliers, the resulting Lagrangian problem is solved by a distributed algorithm, and the Lagrange multipliers (the shadow prices) are updated by a subgradient scheme. For example, the auxiliary problem principle (APP) is used to solve the Lagrangian problem in Ref. 12. The alternating direction method and the predictor–corrector proximal method are applied and compared to the APP method in Ref. 13. These three methods have comparable performance in terms of number of iterations and computation time. The other group of methods uses a variant of Lagrangian relaxation framework, where the KKT system of the subproblem is solved approximately in each iteration [15, 16]. The key observation is that stacking together the KKT conditions of subsystems gives the KKT condition of the entire system. Therefore, if the distributed algorithm converges, the solution thus satisfies the overall KKT condition and is at least a stationary point of the centralized problem. It is worth mentioning that the distributed algorithm frameworks such as the APP or the alternating direction methods are originally proposed for convex optimization problems. The convergence is not guaranteed for general nonconvex problems such as the AC OPF problems.

SECURITY-CONSTRAINED OPTIMAL POWER FLOW PROBLEM

Contingency analysis is routinely performed in the process of economic dispatch. The

goal is to ensure that demand can be satisfied both in the normal case of operation and in the case of contingencies. By contingency, we mean the situation where any one or more components in the power system, such as generators, transmission lines, transformers, or other equipments, experience unexpected failure. The OPF problem with contingency constraints is often referred to as the *security-constrained optimal power flow (SCOPF)*. There are two major types of SCOPF models: the preventive model [18] and the corrective model [19].

The preventive model finds a minimum cost normal case dispatch solution that is also feasible for all prespecified contingency conditions. A general formulation is given in the following equation:

$$\begin{aligned} \min_{\mathbf{x}_0, \dots, \mathbf{x}_C, \mathbf{u}_0} \quad & c(\mathbf{x}_0, \mathbf{u}_0) \\ \text{s.t.} \quad & \mathbf{g}_k(\mathbf{x}_k, \mathbf{u}_0) = 0, \quad k = 0, \dots, C \\ & \mathbf{h}_k(\mathbf{x}_k, \mathbf{u}_0) \leq 0, \quad k = 0, \dots, C, \end{aligned}$$

where $\mathbf{x}_0$ and $\mathbf{x}_k$ represent the state variables in the normal case and the k th contingency, respectively. The state variables include nodal voltage magnitudes and phase angles. $\mathbf{u}_0$ represents the control variable in the normal case, such as the active and reactive powers. As stated earlier, the preventive model requires the normal case control $\mathbf{u}_0$ to be feasible for all C contingencies.

The second type of the SCOPF model is the so-called corrective model, which allows the system operator to readjust control variables after the contingency occurs. The rationale is that the power system components, such as transmission lines and transformers, can usually sustain a short period of overloading without being damaged, which gives the system operator a time window to adjust control variables to eliminate any violations caused by the contingency [19]. The corrective model can be formulated as follows:

$$\begin{aligned} \min_{\mathbf{x}_0, \dots, \mathbf{x}_C, \mathbf{u}_0, \dots, \mathbf{u}_C} \quad & c(\mathbf{x}_0, \mathbf{u}_0) \\ \text{s.t.} \quad & \mathbf{g}_k(\mathbf{x}_k, \mathbf{u}_k) = 0, \quad k = 0, \dots, C \\ & \mathbf{h}_k(\mathbf{x}_k, \mathbf{u}_k) \leq 0, \quad k = 0, \dots, C \\ & |\mathbf{u}_k - \mathbf{u}_0| \leq \bar{\mathbf{u}}_k^{\max}, \quad k = 1, \dots, C. \end{aligned}$$

Here, the system operator has the flexibility to choose a potentially different control variable $\mathbf{u}_k$ for each contingency k . The last constraint imposes the maximum deviation between the normal case control and the postcontingency control. Note that these constraints should be understood component-wise as $|u_{k,i} - u_{0,i}| \leq \bar{u}_{k,i}^{\max}$ for every generator $i \in \mathcal{G}$.

One of the major challenges of SCOPF is its huge dimensionality. For C contingency scenarios, the problem size of the SCOPF problem is roughly $C + 1$ times larger than that of the normal OPF problem. For large-scale power systems involving numerous contingencies, centralized solution algorithms may encounter prohibitive memory usage and long execution times. In the literature, solution approaches include iterative contingency selection schemes, decomposition methods, and network compression methods. It is well known that many postcontingency constraints are redundant, contingency filtering techniques identify and include only those most critical contingencies into the formulation. Benders decomposition algorithms decompose the SCOPF into a master problem and subproblems, where subproblems check the solution feasibility and possibly generate a linear cut for the master problem. The network compression technique aims to reduce the size of the problem based on the observation that the impact of a contingency is in general confined to a localized area of the power grid. See [20] for a recent review on these techniques.

SECURITY-CONSTRAINED UNIT COMMITMENT PROBLEM

Previous sections introduce the fundamental OPF problems. For these OPF problems, the commitment status of generators is assumed to be known and fixed over the dispatch period. The other fundamental problem in power systems operation is the UC problem, where the commitment status of generators is the critical decision to be made, together with the dispatch decision for generation power output.

The UC problem is usually solved in a day-ahead time framework for the following

24 h of the day and thus involves a multiperiod decision-making, whereas the OPF-based economic dispatch is usually solved in real time for one single period (for example, every 5 min in the ISO New England system). Thus, in addition to all the constraints in the economic dispatch problem, the multiperiod unit commitment also requires intertemporal constraints such as constraints on ramping capabilities of generators and constraints on the minimum time that a generator has to remain on (off) after a starting up (a shutting down).

In the process of UC, it is also important to account for various uncertainties such as forecast error for load and renewable energy supply and unexpected outages of generators and transmission lines. To deal with unexpected outages, the security constraints as described in the section titled “Security-Constrained Optimal Power Flow Problem” are incorporated in the UC problem. To account for the load and supply uncertainty, a widely adopted approach is to keep a certain amount of generation capacity available for fast response to sudden unexpected changes in load and supply. This amount of standby capacity is called *reserves*, which are further classified into different categories based on the speed of its response, such as ten-minute spinning reserve (TMSR), ten-minute nonspinning reserve (TMNSR), and thirty-minute operating reserve (TMOR).

Incorporating all of the above-mentioned modeling considerations, the security-constrained unit commitment (SCUC) problem is formulated as the following mixed-integer optimization problem [21, 22]:

$$\min_{\mathbf{x}, \mathbf{u}, \mathbf{v}, \mathbf{p}, \mathbf{r}} \sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{G}} (f_i^t(x_i^t, u_i^t, v_i^t) + c_i^t(p_i^t)) \quad (9a)$$

$$\text{s.t. } x_i^{t-1} - x_i^t + u_i^t \geq 0, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, \quad (9b)$$

$$x_i^t - x_i^{t-1} + v_i^t \geq 0, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, \quad (9c)$$

$$\begin{aligned} x_i^t - x_i^{t-1} &\leq x_i^{\tau}, \\ \forall \tau &\in [t + 1, \min\{t + \text{MinUp}_i - 1, T\}], \\ t &\in [2, T], i \in \mathcal{G}, \end{aligned} \quad (9d)$$

$$\begin{aligned}
x_i^{t-1} - x_i^t &\leq 1 - x_i^t, \\
\forall \tau \in [t+1, \min\{t + \text{MinDw}_i - 1, T\}], t \in [2, T], \\
i \in \mathcal{G}
\end{aligned} \quad (9e)$$

$$\sum_{i \in \mathcal{G}} p_i^t = \sum_{j \in \mathcal{D}} \bar{d}_j^t, \quad \forall t \in \mathcal{T}, \quad (9f)$$

$$\begin{aligned}
-RD_i x_i^t - SD_i v_i^t &\leq p_i^t - p_i^{t-1} \leq RU_i x_i^{t-1} \\
&+ SU_i u_i^t, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, \quad (9g)
\end{aligned}$$

$$\begin{aligned}
-f_{l,k}^{\max} &\leq \mathbf{a}_{l,k}^T (\mathbf{p}^t - \mathbf{d}^t) \leq f_{l,k}^{\max}, \\
\forall t \in \mathcal{T}, l \in \mathcal{C}_k, k \in \mathcal{L}, \quad (9h)
\end{aligned}$$

$$p_i^{\min} \leq p_i^t + \sum_{a \in \mathcal{A}} r_{i,a}^t \leq p_i^{\max}, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, \quad (9i)$$

$$p_i^{\min} x_i^t \leq p_i^t \leq p_i^{\max} x_i^t, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, \quad (9j)$$

$$\sum_{i \in \mathcal{G}, a \in \mathcal{A}_k} r_{i,a}^t \geq \bar{r}_k^t, \quad \forall t \in \mathcal{T}, k \in \mathcal{N}_r, \quad (9k)$$

$$\sum_{a \in \mathcal{A}_k} r_{i,a}^t \leq \bar{r}_{i,k}^t, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}, k \in \mathcal{N}_r, \quad (9l)$$

$$x_i^t, u_i^t, v_i^t \in \{0, 1\}, \quad \forall i \in \mathcal{G}, t \in \mathcal{T}. \quad (9m)$$

The decision variables include binary variables x_i^t, u_i^t, v_i^t for commitment decisions and continuous variables p_i^t and $r_{i,a}^t$ for generation and reserve decisions, where $x_i^t = 1$ if generator i is producing electricity, that is, in the on state, at time t , and $x_i^t = 0$ otherwise; $u_i^t = 1$ if generator i is turned on from the off state at time t ; $v_i^t = 1$ if generator i is turned off at time t ; p_i^t is the amount of electricity produced by generator i at time t ; and $r_{i,a}^t$ is the amount of reserve provided by generator i for reserve type a at time t .

The parameters in the above-mentioned model are explained later. The function $f_i^t(x_i^t, u_i^t, v_i^t)$ is the total fixed cost of generator i at time t in the horizon $\mathcal{T}$, including startup cost, shutdown cost, and other fixed costs. $c_i^t(p_i^t)$ is the operating cost, which is usually

approximated as a convex piece-wise linear function of the active power output p_i^t . $\bar{d}_j^t$ is the forecast nodal load at bus j , time t . RU_i and RD_i are, respectively, the ramp-up and ramp-down rates of generator i , and SU_i and SD_i are the ramp-up and ramp-down rates when generator i is starting up and shutting down, respectively.

$\mathbf{a}_{l,k} \in \mathbb{R}^{|\mathcal{V}|}$ is the shift factor vector of line l in the k th contingency where line k is offline. The i -th component of $\mathbf{a}_{l,k}$ is defined as the change of power flow on line l if a unit of power is injected at bus i and taken out at the reference bus. $\mathcal{C}_k$ is the set of remaining lines when line k is tripped. $\bar{r}_k^t$ is the system level reserve requirement for reserve type k at time t . $\mathcal{N}_r$ is the set of all reserve types such as TMSR, TMNSR, and TMOR. $\bar{r}_{i,a}^t$ is the maximum amount of reserve type a that generator i can provide at time t . $\mathcal{A}_k$ is the set of reserve types that generator k can provide.

Constraints (Eqs 9b and 9c) represent logic relations between on and off status and the turn-on and turn-off actions. Constraints (Eqs 9d and 9e) restrict the minimum up and down times for each generator. Constraint (Eq. 9f) enforces energy balance in each time period. Constraint (Eq. 9g) is the ramping constraint, which enforces the ramp-up and ramp-down limits of each generator. The ramping constraint says that when the generator is already on at time period t , the ramp-up and ramp-down rates at that time cannot exceed RU_i and RD_i , respectively; when the generator is being turned on or turned off at time period t , the ramping rates cannot exceed another set of limits SU_i and SD_i . Constraint (Eq. 9h) is the linearized power flow equations using shift factors for the i th contingency, which means the i th transmission line is tripped off, and $i = 0$ represents the normal case.

Constraint (Eq. 9i) limits the total production and reserve for each generator. Constraint (Eq. 9j) limits the production level of each generator. Constraint (Eq. 9k) is the system reserve requirement for reserve category k at time t . Constraint (Eq. 9l) provides an upper bound on generator i 's reserve capacity.

ADAPTIVE ROBUST OPTIMIZATION FOR SCUC UNDER UNCERTAINTY

As discussed in the section titled “Security-Constrained Unit Commitment Problem,” there are various uncertainties in the daily operation of power systems, among which an increasingly significant source of uncertainty is from the generation side. In particular, renewable energy resources using wind and solar power are intrinsically intermittent and uncertain. The forecast of these renewable resources is much more challenging than the forecast of traditional load. Furthermore, the penetration level of renewable energy in the power grid is increasing rapidly in many major power systems in the world, which makes the associated supply uncertainty an emerging threat to reliable system operations.

The SCUC model introduced in the section titled “Security-Constrained Unit Commitment Problem” uses the reserve approach to deal with uncertainties. This approach relies on predetermined reserve requirements, which do not reflect the fast changing uncertainty in the operational environment. A popular alternative is the stochastic-programming-based unit commitment model. Stochastic UC models explicitly consider scenarios of uncertainties and generate a UC decision with a minimum expectation cost over the considered scenarios [23]. A significant challenge of the stochastic programming approach is the representation of uncertainty, in particular, the difficulty of scenarios selection in a large power system; the other challenge, perhaps even more formidable, is the computational burden of the resulting large-scale mixed-integer optimization problem.

In this section, we introduce a new direction of study on UC under severe uncertainty using the robust optimization-based approach. Robust optimization has recently emerged as a rich and powerful paradigm for decision-making under uncertainty [24]. The basic idea of robust optimization is based on two concepts: uncertainty sets and robust constraints. An uncertainty set is a deterministic set that describes the uncertain parameters. The simplest example is an interval of

the uncertainty, for instance wind power output of a wind farm. This interval describes all possible values of the wind power. As wind power is uncertain, any constraint in the original deterministic UC model (9) that involves wind power needs special attention. In particular, we want a robust version of these constraints, which enforces that the UC and dispatch decisions satisfy these constraints for any realization of wind power in the uncertainty set. This is the so-called robust constraints. A UC model with uncertainty sets and robust constraints is a robust UC model.

There is much more to the above-mentioned simplistic setting of robust UC models. In the section titled “Adaptive Robust UC Model,” we introduce an adaptive robust optimization-based UC model, which has more sophisticated optimization structure and more realistic uncertainty sets. Then, we present an efficient solution method for this model in the section titled “Solution Method to Solve Adaptive Robust Model.”

Adaptive Robust UC Model

In this section, we consider the net nodal load, which combines the traditional load and wind power output as negative load. The net nodal load, therefore, is highly uncertain. The interval uncertainty set is a very simplistic example of uncertainty sets. Consider the following uncertainty set of net load at each time period t :

$$\begin{aligned} \mathcal{D}^t(\bar{\mathbf{d}}_i, \hat{\mathbf{d}}_i^t, \Delta^t) &:= \{\mathbf{d}^t \in \mathbb{R}^{N_d} : \\ &\sum_{i \in \mathcal{N}_d} \frac{|d_i^t - \bar{d}_i^t|}{\hat{d}_i^t} \leq \Delta^t, \\ &d_i^t \in [\bar{d}_i^t - \hat{d}_i^t, \bar{d}_i^t + \hat{d}_i^t], \forall i \in \mathcal{N}_d\}, \quad (10) \end{aligned}$$

where $\mathcal{N}_d$ is the set of nodes that have uncertain injections, N_d is the number of such nodes, $\mathbf{d}^t = (d_i^t, i \in \mathcal{N}_d)$ is the vector of uncertain net injections at time t , $\hat{d}_i^t$ is the nominal value of the net injection of node i at time t , $\bar{d}_i^t$ is the deviation from the nominal net injection value of node i at time t , the interval $[\bar{d}_i^t - \hat{d}_i^t, \bar{d}_i^t + \hat{d}_i^t]$ is the range of the uncertain d_i^t , and the inequality in Equation (10) controls

the total deviation of all injections from their nominal values at time t . The parameter Δ^t is the “budget of uncertainty,” taking values between 0 and N_d . When $\Delta^t = 0$, the uncertainty set $\mathcal{D}^t = \{\bar{\mathbf{d}}\}$ is a singleton, corresponding to the nominal deterministic case. As Δ^t increases, the size of the uncertainty set $\mathcal{D}^t$ enlarges. This means that larger total deviation from the expected net injection is considered, so that the resulting robust UC solutions are more conservative and the system is protected against a higher degree of uncertainty. When $\Delta^t = N_d$, $\mathcal{D}^t$ equals to the entire hypercube defined by the intervals for each d_i^t for $i \in \mathcal{N}_d$.

Now, we formulate the adaptive robust UC model as follows:

$$\begin{aligned} \min_{\mathbf{x}} \quad & (\mathbf{c}^T \mathbf{x} + \max_{\mathbf{d} \in \mathcal{D}} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{d})} \mathbf{b}^T \mathbf{y}) \\ \text{s.t.} \quad & \mathbf{F}\mathbf{x} \leq \mathbf{f}, \mathbf{x} \text{ binary}, \end{aligned} \quad (11)$$

where $\mathbf{x}$ is the vector of commitment-related decisions, $\mathbf{y}$ is the vector of dispatch-related variables, $\mathcal{D}$ is the Cartesian product of nodal load uncertainty sets over time, $\Omega(\mathbf{x}, \mathbf{d}) = \{\mathbf{y} : \mathbf{H}\mathbf{y} \leq \mathbf{h}, \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} \leq \mathbf{g}, \mathbf{I}_u \mathbf{y} = \mathbf{d}\}$ is the set of feasible dispatch solutions for a fixed commitment decision $\mathbf{x}$ and nodal net injection realization $\mathbf{d}$, the constraints $\mathbf{H}\mathbf{y} \leq \mathbf{h}, \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} \leq \mathbf{g}, \mathbf{I}_u \mathbf{y} = \mathbf{d}$ are a matrix representation of constraints (Eqs 9f–9l), and constraints $\mathbf{F}\mathbf{x} \leq \mathbf{f}$ is a matrix representation of commitment constraints (Eqs 9b–9e).

From this formulation, we can see that the commitment decision $\mathbf{x}$ considers all possible future net load represented in the uncertainty set $\mathcal{D}$. Such a commitment solution remains feasible, thus *robust*, to any realization of the uncertain net load. In comparison, the traditional UC solution only guarantees feasibility for a single nominal net load, whereas the stochastic optimization UC solution only considers a finite set of preselected scenarios of the uncertain net load. Furthermore, in this formulation, the optimal second-stage decision $\mathbf{y}$ is a function of the uncertain net load $\mathbf{d}$, where the functional form $\mathbf{y}(\mathbf{d})$ is implicitly determined by the economic dispatch problem $\min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{d})} \mathbf{b}^T \mathbf{y}$. The dispatch solution is thus *fully adaptive* to any realization of the uncertainty.

Solution Method to Solve Adaptive Robust Model

This section outlines an efficient algorithm to solve the adaptive robust UC model (Eq. 11) proposed in Ref. 25; similar algorithms are also proposed in Refs 26 and 27. Observe that the adaptive robust UC model (11) is a two-stage problem, where the first stage finds the optimal commitment decision and the second stage finds the worst-case dispatch cost under a fixed commitment solution. The proposed solution method is a two-level algorithm. The outer level uses a modified Benders decomposition type method that uses cuts generated from the inner level algorithm. The inner level solves the second-stage problem $\max_{\mathbf{d} \in \mathcal{D}} \min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{d})} \mathbf{b}^T \mathbf{y}$, which can be reformulated either as a bilinear optimization problem by dualizing the inner dispatch problem $\min_{\mathbf{y} \in \Omega(\mathbf{x}, \mathbf{d})} \mathbf{b}^T \mathbf{y}$ [25] or as a mixed-integer linear optimization problem by introducing binary variables and big- M constants to linearize the bilinear terms [26].

The modification to the traditional Benders decomposition proposed in Ref. [25] is the following: after solving the inner problem, the constraints of the inner dispatch problem associated with the obtained worst-case net load are added to the outer problem. This approach turns out to significantly speed up the convergence of the algorithm. It is formalized and rigorously analyzed in Ref. [27].

Modified Benders Decomposition Algorithm:

Step 1: Solve the following outer level master problem:

$$\begin{aligned} \min_{\mathbf{x}, \alpha, \mathbf{y}^i, \forall i=1, \dots, k-1} \quad & \mathbf{c}^T \mathbf{x} + \alpha \\ \text{s.t.} \quad & \alpha \geq \lambda_l^T (\mathbf{A}\mathbf{x} - \mathbf{g}) - \varphi_l^T \mathbf{h} + \eta_l^T \mathbf{d}_l, \\ & \forall l \leq k, \\ & \mathbf{F}\mathbf{x} \leq \mathbf{f}, \mathbf{x} \text{ binary}, \\ & \mathbf{y}^i \in \Omega(\mathbf{x}, \mathbf{d}^i), \forall i = 1, \dots, k-1. \end{aligned} \quad (12)$$

Let $(\mathbf{x}_k, \alpha_k)$ be the optimum. Set $L^{\text{BD}} = \mathbf{c}^T \mathbf{x}_k + \alpha_k$. The inequality (Eq. 12) is the cut generated from the second-stage problem.

Step 2: For the fixed commitment decision $\mathbf{x}_k$, solve the second-stage problem. Denote its optimal objective value as $R(\mathbf{x}_k)$, and the obtained worst-case net load as $\mathbf{d}^k$. Add the constraints with $\mathbf{d}^k$, namely $\mathbf{y}^k \in \Omega(\mathbf{x}, \mathbf{d}^k)$, to the outer problem. Set $U^{\text{BD}} = \mathbf{c}^T \mathbf{x}_k + R(\mathbf{x}_k)$.

Step 3: If $U^{\text{BD}} - L^{\text{BD}} < \varepsilon$, stop and return $\mathbf{x}_k$. Otherwise, let $k = k + 1$, and go to Step 1.

Extensive computational experiments have been conducted on some large-scale power systems, such as the ISO New England's power system [25]. Comparing to the reserve adjustment approach used in the current practice, the adaptive robust UC model demonstrates better economic efficiency in terms of lower average commitment and dispatch costs, significantly reduced volatility of the dispatch cost, and robustness against different uncertainty distributions.

CONCLUSIONS

In this article, we have discussed basic optimization models and the most recent advances for the OPF and the unit commitment problem, two of the fundamental decision-making problems in short-term power system operations. In particular, advanced global optimization techniques for solving the OPF problem are presented. An adaptive robust optimization model and solution methods for the UC problem are introduced, which provide a new, effective framework for power system operations under uncertainty. We have also discussed contingency analysis for large-scale power systems and distributed optimization schemes for decentralized control of the power systems. In conclusion, modern optimization methods play a central role in power system operations. Further advances are needed to meet new challenges arising in the fast-evolving modern power systems.

SPANISH SOCIETY OF STATISTICS AND OPERATIONS RESEARCH

IGNACIO GARCIA JURADO
Department of Mathematics,
Coruna University, Coruna,
Spain

SEIO (www.seio.es), which stands for Sociedad de Estadística e Investigación Operativa, is the Spanish Society of Statistics and Operations Research. It was founded in February 12, 1962, in Madrid, in the facilities of CSIC, Consejo Superior de Investigaciones Científicas (the Spanish Science Foundation). Fifty-two persons, including academics and practitioners, participated in the inaugural meeting. Originally, SEIO was only concerned with operations research and its promotion within Spain. In fact, from 1962 to 1984, SEIO stood for Sociedad Española de Investigación Operativa (Spanish Society of Operations Research), and only in December 20, 1984, SEIO changed its name, aims and statutes, and included statistics in its list of key fields. Nowadays, it is a scientific society, which aims to promote and develop the theory, methodology, and applications of statistics and operations research mainly, but not only, within Spain.

The first President of SEIO was Fermín de la Sierra (from February 12, 1962, to March 31, 1969) and, after him until today, the Presidents have been Sixto Ríos (1969–1984), Pilar Ibarrola (1984–1986), Marco A. López Cerdá (1986–1989), Daniel Peña (1989–1992), Elías Moreno (1992–1994), Jesús Pastor (1994–1998), Rafael Infante (1998–2001), Pedro Gil (2001–2004), Domingo Morales (2004–2007), and Ignacio García Jurado (the current president). According to the statutes, a president is elected for a term of three years. Immediately after the election, he or she serves as the elected president for one and a half years; then he or she is the president for three years, and finally he or she serves as the past president for one and a half years.

Currently, the elected president of SEIO is José M. Angulo, who will be the president in September 2010.

SEIO has also a vice president of operations research and a vice president of statistics. It is governed by an Executive Committee formed by the president, the past president or the elected president, the two vice presidents, the secretary, and five other elected members. The executive committee is advised by two academic committees when dealing with scientific issues regarding operations research or statistics. Each academic committee is chaired by the corresponding vice president and has two other elected members. SEIO also has commissions which are nominated by the executive committee to promote activities in the key areas. Nowadays, there are three such commissions: the commissions of education and dissemination, cooperation and development, and universities.

Currently, SEIO has about 700 ordinary members. It has also 17 institutional members including the Instituto Nacional de Estadística (the Statistical Office of Spain).

SEIO organizes a national conference every one and a half years. In 2009 it organized the 31st National Conference in Murcia (Spain). In the last national conferences, the number of participants was about 400 and the number of lectures delivered was about 300.

SEIO publishes two journals: *Test*, a journal of statistics, and *Top*, a journal of operations research. The history of these two journals is as follows. In 1950, Sixto Ríos founded the journal *Trabajos de Estadística*. In 1963, *Trabajos de Estadística* changed its name to *Trabajos de Estadística e Investigación Operativa* and became the official journal of SEIO. In 1986 *Trabajos de Estadística e Investigación Operativa* was split into two different journals: *Trabajos de Estadística*, focused on statistics, and *Trabajos de Investigación Operativa*, focused on operations research. In 1992 *Trabajos de Estadística* became *Test* and started

publishing papers only in English. In 1993 *Trabajos de Investigación Operativa* went through a similar process: it became *Top* and started publishing papers only in English. Since 2007 *Test* and *Top* are published and distributed by Springer, though they continue being the two official journals of SEIO. The editors of *Test* have been José M. Bernardo (1992–1996), Antonio Cuevas and Wenceslao González Manteiga (1997–2001), Enrique Castillo and Juan A. Cuesta (2002–2004), and M. Ángeles Gil and Leandro Pardo (2005–2008). Since January 2009 its editors are Ricardo Cao and Domingo Morales. The editors of *Top* have been Jaume Barceló and Laureano Escudero (1993–2000) and Marco A. López Cerdá and Ignacio García Jurado (2001–2006). Since January 2007 its editors are Emilio Carrizosa and Justo Puerto. Nowadays *Test* and *Top* are well-established scientific journals in their respective fields; for instance, in the science edition of the Journal Citation Reports 2008, produced by Thomson Reuters, *Top* has an impact factor 0.694 and occupies position 45 in the list of 64 journals of operations research and management science, whereas *Test* has an impact factor 0.930 and occupies position 50 in the list of 92 journals of statistics and probability.

SEIO also distributes information and promotes both dissemination and applications of statistics and operations research. To that aim, it currently maintains a web site, whose address is www.seio.es, produces the electronic bulletin of general information *InfoSEIO*, and publishes *BEIO*, a bulletin which mainly collects papers on applications of statistics and operations research. *BEIO* is indexed in MathScinet and Zentralblatt MATH. Its current editor is M. Carmen Pardo.

Since 1984, SEIO and Fundación Ramiro Melendreras have jointly awarded a prize for young researchers. The Ramiro Melendreras Prize is given at the closing session of the national conference and it has become an important prize in its field within Spain. The winners of this prize have been Wenceslao González Manteiga (1984), Domingo Morales (1985), David Ríos (1986), Ignacio García Jurado (1988), Ricardo Cao (1989), Luciano Méndez Naya (1991), José A. Vilar (1992), J.J. Salazar (1995), M. Carmen Pardo (1997), Joaquín Sánchez Soriano (1998), Jacobo de Uña (2000), Isabel Molina (2001), Javier Toledo (2003), Alberto Olivares (2004), Pedro Terán (2006), Enrique Chacón (2007), and Sergio García Quiles (2009).

SEIO encourages the existence of working groups to support the research activities of its members. Currently SEIO has six working groups in the following fields: location theory, game theory, multicriteria decision analysis, classification and multivariate analysis, teaching of statistics and operations research, and functional data analysis.

SEIO has well-established relations with the most relevant international scientific organizations in the fields of statistics and operations research. In particular, SEIO is a member of the International Federation of Operational Research Societies (IFORS), Association of European Operational Research Societies (EURO), Association of Latin–Iberoamerican Operational Research Societies (ALIO), International Statistical Institute (ISI), and European Courses on Advances Statistics (ECAS). SEIO is also a member of the European Mathematical Society (EMS), and the Spanish Committee of Mathematics (CEMAT).

Today, SEIO is a very active scientific society and the most important Spanish organization which promotes operations research.

INTRODUCTION

We consider the following form of a mixed integer program (MIP):

$$\begin{aligned} \min \quad & c^T y \\ \text{s.t.} \quad & y \in \{x \in P : x_j \text{ integer for all } j \in N_I\}, \end{aligned}$$

where $P \subseteq \mathbb{R}^n$ is a polyhedron describing the set of feasible solutions to the linear program (LP) relaxation of MIP, $N := \{1, 2, \dots, n\}$ is used to index the variables, and $N_I \subseteq N$ denotes those variables that are required to be integers. The set $P_I := \{x \in P : x_j \text{ integer for all } j \in N_I\}$ denotes the set of mixed integer points in P . We assume that P is a *rational* polyhedron, that is, that P can be described with inequalities that are defined using only rational numbers.

The following concept is key in the remainder. A *disjunction* with q terms is an expression of the form $D^1 x \leq d^1 \vee D^2 x \leq d^2 \vee \dots \vee D^q x \leq d^q$, where for every $i \in \{1, 2, \dots, q\}$, the matrix D^i and the vector d^i define the linear system $D^i x \leq d^i$ in n variables. A vector $y \in \mathbb{R}^n$ satisfies this disjunction if $D^i y \leq d^i$ for some $i \in \{1, 2, \dots, q\}$.

Let $(\pi, \pi_0) \in \mathbb{Z}^{n+1}$ be arbitrary. If we assume $\pi_j = 0$ for all continuous variables $j \in N \setminus N_I$, then the *split disjunction* $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ is satisfied by all mixed integer points $x \in P_I$. The set of all split disjunctions will be denoted:

$$\Pi := \{(\pi, \pi_0) \in \mathbb{Z}^{n+1} : \pi_j = 0 \text{ for } j \in N \setminus N_I\}.$$

The idea of using disjunctions to derive cutting planes for MIP was first considered by

Balas [1]. Balas showed how to use an optimal basis for the LP relaxation of MIP, together with a disjunction to obtain a cut that was named the *intersection cut*. In a later paper [2], Balas introduced *disjunctive programs*, where disjunctions were considered together with polyhedra to obtain valid cuts for MIP. A disjunctive program is an optimization problem defined from a polyhedron and a disjunction. The problem is to find a point in the polyhedron that satisfies the disjunction and has the best possible objective.

The special case of split disjunctions was first studied by Cook *et al.* [3], where the term *split cuts* was introduced. Given the mixed integer program (MIP), the *split closure* with reference to P and N_I was analyzed. The split closure with reference to P and N_I is the set obtained from P by adding *all* split cuts that can be derived by considering *all* split disjunctions in Π , and it was shown in Cook *et al.* [3] that the split closure with reference to P and N_I is a polyhedron. Since then, several different proofs have been given to show this fact [4–6].

Strong relationships have been established between split cuts and other classes of cutting-planes; see Cornuéjols and Li [7] for an excellent description of the relationships between different classes of cutting planes. Split cuts have been shown to be equivalent to mixed integer Gomory cuts and mixed integer rounding cuts [8]. Furthermore, it has been shown that every split cut is an intersection cut, and that every split cut can be obtained from a basis of the LP relaxation [4,9].

Recently, computational experiments have been performed to measure how tight an approximation the split closure gives to the mixed integer hull on a number of test problems. Balas and Saxena [10] formulated a parametric MIP for computing a split cut that is violated by a given point; that is, for solving the separation problem for split cuts. Although the separation problem for split cuts is known to be NP-complete [11], Balas and Saxena managed to compute the split

Figure 1. Effect of applying a split disjunction to a polytope. (a) Polytope P , (b) The sets P_π^1 and P_π^2 , and (c) The disjunctive hull.

closure on several test problems and they demonstrated that the split closure often provides a very tight approximation. Dash *et al.* [5] provided a different formulation of the separation problem and they compared the strength of the split closure to the strength of other classes of cutting-planes.

The remainder is organized as follows: In the section titled “Split Disjunctions and Polyhedra,” we describe the basic operation of applying a split disjunction to obtain a tighter approximation of P_I than P . In the section titled “Split Cuts from Bases of the LP Relaxation,” we derive split cuts from split disjunctions and bases of the LP relaxation of MIP. Finally, in the section titled “Computational Results on the Split Closure,” we present computational results to measure the quality of the split closure as an approximation to the set of mixed integer point in P_I .

SPLIT DISJUNCTIONS AND POLYHEDRA

We now present the operation of using a split disjunction to construct a tighter approximation of a mixed integer set. To illustrate the construction, we first give an example in dimension two.

Example 1. Consider the polyhedron P in $\mathbb{R}^2$ shown in Fig. 1(a), and suppose x_1 and x_2 are both required to be integer; that is, suppose $N = N_I = \{1, 2\}$.

In Fig. 1(b), the two parallel lines $\pi_1 x_1 + \pi_2 x_2 = \pi_0$ and $\pi_1 x_1 + \pi_2 x_2 = \pi_0 + 1$ corresponding to a split disjunction $\pi^T x \leq$

$\pi_0 \vee \pi^T x \geq \pi_0 + 1$ are shown. This split disjunction defines the two subsets $P_\pi^1 := \{x \in P : \pi^T x \leq \pi_0\}$ and $P_\pi^2 := \{x \in P : \pi^T x \geq \pi_0 + 1\}$ of P that are shown by the two shaded regions in Fig. 1(b). Observe that since no integer point $x \in \mathbb{Z}^2$ satisfies $\pi_0 < \pi^T x < \pi_0 + 1$, every integer point in P belongs to the set $P_\pi^1 \cup P_\pi^2$. Therefore, the valid inequalities for $P_\pi^1 \cup P_\pi^2$ are valid for the integer points in P .

Since an inequality is valid for $P_\pi^1 \cup P_\pi^2$ if and only if it is valid for $\text{Conv}(P_\pi^1 \cup P_\pi^2)$, the valid inequalities for $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ are valid inequalities for the integer points in P . The set $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ is shown by the shaded polygon in Fig. 1(c), and we call this set the *disjunctive hull* defined by the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. Observe that there are two valid inequalities for $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ that are not valid for P , and these inequalities can therefore be used as cuts to cut off fractional points in P .

We now generalize the construction presented in Example 1 to any mixed integer set P_I . Let $(\pi, \pi_0) \in \Pi$ be arbitrary. We have that every mixed integer point $x \in P_I$ satisfies $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. As in Example 1, the disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ defines two subsets $P_\pi^1 := \{x \in P : \pi^T x \leq \pi_0\}$ and $P_\pi^2 := \{x \in P : \pi^T x \geq \pi_0 + 1\}$ of P , and every mixed integer point in P_I belongs to $P_\pi^1 \cup P_\pi^2$. It follows that the valid inequalities for $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ are valid for P_I . As in Example 1, we call the set $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ the *disjunctive hull* defined by $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. We will not present the proof here, but it can be shown that

the disjunctive hull defined from any split disjunction is a polyhedron.

Observe that *all* split disjunctions $(\pi, \pi_0) \in \Pi$ potentially can tighten the LP relaxation of MIP; that is, we have $P_I \subseteq \text{Conv}(P_\pi^1 \cup P_\pi^2) \subseteq P$ for all $(\pi, \pi_0) \in \Pi$. The intersection of *all* disjunctive hulls over *all* split disjunctions $(\pi, \pi_0) \in \Pi$ therefore gives the tightest possible relaxation of P_I that can be obtained with split cuts

$$\text{SC} := \bigcap_{(\pi, \pi_0) \in \Pi} \text{Conv}(P_\pi^1 \cup P_\pi^2).$$

The set SC is called the *split closure* with reference to P and N_I . Observe that the split closure with reference to P and N_I is defined as the intersection of an infinite number of polyhedra. It is therefore not obvious whether SC is a polyhedron. It was first shown by Cook *et al.* that SC is a polyhedron [3].

SPLIT CUTS FROM BASES OF THE LP RELAXATION

The objective in this section is to characterize the geometry of the split cuts that can be derived from a basis of the LP relaxation. Central to this objective is the special case when P is a translate of a polyhedral cone, which we will consider in the section titled “Split Cuts from Translates of Polyhedral Cones.” In the section titled “Split Cuts from Bases and Split Cuts from Polyhedra,” we apply the results of the previous section to obtain cuts from a basis, and we relate these

cuts to the split closure with reference to P and N_I . We show how to strengthen a split disjunction in the section titled “Strengthening Split Disjunctions.” In the section titled “Mixed Integer Gomory Cuts from Rows of the Simplex Tableau,” we show how mixed integer Gomory cuts can be viewed as split cuts.

Split Cuts from Translates of Polyhedral Cones

We now consider the special case when the LP relaxation P is defined from a translate of a polyhedral cone. The reason is, as we will explain later, that every split cut can be obtained from an object of this type. Furthermore, the formulas for computing a split cut from a simplex table will follow directly from the results presented in this section.

A *polyhedral cone* is a cone that is finitely generated, that is a set of the form $C := \{x \in \mathbb{R}^m : x = \sum_{j \in J} s_j r^j \text{ and } s \geq 0\}$, where J is a finite index set and $r^j \in \mathbb{R}^m$ for $j \in J$. In other words, C is the set of points $x \in \mathbb{R}^m$ that can be written as a nonnegative combination of the vectors r^j for $j \in J$. A *translate* of a polyhedral cone C is a set that can be written as the sum of a point $\bar{x} \in \mathbb{R}^m$ and a polyhedral cone; that is, a set of the form $\bar{x} + C$. In the following, we will call the vectors r^j for $j \in J$ for *rays*. Figure 2(a) gives an example of a translate of a polyhedral cone defined from two rays r^1 and r^2 and a point $\bar{x} \in \mathbb{R}^2$.

Figure 2. Deriving a split cut from a translated cone. (a) A polyhedron P^x of the form $P^x = \bar{x} + \text{Cone}(r^1, r^2)$, (b) The polyhedron P^x and a split disjunction, and (c) The disjunctive hull and the split cut.

In this section we consider the special case when the LP relaxation P has the form

$$P = \{(x, s) \in \mathbb{R}^m \times \mathbb{R}^{|J|} : x = \bar{x} + \sum_{j \in J} s_j r^j \text{ and } s \geq 0\}$$

and $P_I = \{(x, s) \in P : x \text{ is an integer}\}$. Observe that the projection of P onto the space of the x variables is a translate of a polyhedral cone. The variables s_j for $j \in J$ are the multipliers on the rays in the conic combinations, and they are considered continuous variables.

The geometry of the sets P and P_I will now be explained by considering their projection onto the space of the x variables, that is by considering the sets

$$P^x := \{x \in \mathbb{R}^m : \exists s \in \mathbb{R}^{|J|} \text{ s.t. } (x, s) \in P\}$$

$$\text{and } P_I^x := P^x \cap \mathbb{Z}^m.$$

Observe that P_I^x is a pure integer set; that is, all variables are required to be integers. Furthermore, the linear relaxation P^x of P_I^x is the translate $P^x = \bar{x} + C$ of the polyhedral cone $C = \{x \in \mathbb{R}^m : x = \sum_{j \in J} s_j r^j \text{ and } s \geq 0\}$.

We next show how split disjunctions can be used to derive split cuts for P_I . To illustrate the construction, we first give an example where the sets P^x and P_I^x are two dimensional.

Example 2. Consider the translated polyhedral cone P^x in Fig. 2(a). Two parallel lines $\pi^T x = \pi_0$ and $\pi^T x = \pi_0 + 1$ corresponding to a split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ are drawn in Fig. 2(b). As in Example 1, the split disjunction defines two subsets $\{x \in P^x : \pi^T x \leq \pi_0\}$ and $\{x \in P^x : \pi^T x \geq \pi_0 + 1\}$ of P^x (the two shaded areas in Fig. 2(b)). The disjunctive hull corresponding to $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ is the shaded area in Fig. 2(c).

Observe that only one inequality is needed to describe the disjunctive hull (the split cut given in Fig. 2(c)). Also observe that, if we let x^1 denote the point on the halfline $\{\bar{x} + \alpha r^1 : \alpha \geq 0\}$ that satisfies $\pi^T x^1 = \pi_0$, and if we let x^2 denote the point on the halfline $\{\bar{x} + \alpha r^2 : \alpha \geq 0\}$ that satisfies $\pi^T x^2 = \pi_0 + 1$, then the split cut in Fig. 2(c) corresponds to the line that passes through x^1 and x^2 . In other words, the split cut in the figure can be

obtained by first identifying the two points x^1 and x^2 , and then computing the line that passes through x^1 and x^2 .

We next generalize the construction of a split cut given in Example 2. Let $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ be a valid split disjunction. We assume $\bar{x}$ does not satisfy the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$, that is we assume $\pi_0 < \pi^T \bar{x} < \pi_0 + 1$ (we will show below that no split cut can be derived from a split disjunction that is satisfied by $\bar{x}$). Define $\epsilon_\pi := \pi^T \bar{x} - \pi_0$ to be the amount by which $\bar{x}$ violates the first term of the split disjunction.

Now let $j \in J$ be arbitrary. For $\alpha \geq 0$, define $x^j(\alpha) := \bar{x} + \alpha r^j$. We are interested in the smallest value $\alpha \geq 0$ for which $x^j(\alpha)$ satisfies the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$.

There are three cases: either the halfline $\{x^j(\alpha) : \alpha \geq 0\}$ intersects the hyperplane $\pi^T x = \pi_0$, or the halfline $\{x^j(\alpha) : \alpha \geq 0\}$ intersects the hyperplane $\pi^T x = \pi_0 + 1$, or the halfline $\{x^j(\alpha) : \alpha \geq 0\}$ does not intersect any of these two hyperplanes. In Example 2, the halfline $\{x^1(\alpha) : \alpha \geq 0\}$ intersects the hyperplane $\pi^T x = \pi_0$, and the halfline $\{x^2(\alpha) : \alpha \geq 0\}$ intersects the hyperplane $\pi^T x = \pi_0 + 1$.

The specific value of $\alpha \geq 0$ for which $x^j(\alpha)$ satisfies the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ can now be computed. If $\pi^T r^j < 0$, then $x^j(\alpha)$ is on the hyperplane $\pi^T x = \pi_0$ for $\alpha = -\frac{\epsilon_\pi}{\pi^T r^j}$, if $\pi^T r^j > 0$, then $x^j(\alpha)$ is on the hyperplane $\pi^T x = \pi_0 + 1$ for $\alpha = \frac{1 - \epsilon_\pi}{\pi^T r^j}$, and if $\pi^T r^j = 0$, then $x^j(\alpha)$ is not on any of the hyperplanes $\pi^T x = \pi_0$ and $\pi^T x = \pi_0 + 1$ for any $\alpha \geq 0$. Hence, if we define

$$\alpha_\pi^j := \begin{cases} -\frac{\epsilon_\pi}{\pi^T r^j} & \text{if } \pi^T r^j < 0, \\ \frac{1 - \epsilon_\pi}{\pi^T r^j} & \text{if } \pi^T r^j > 0, \\ +\infty & \text{otherwise,} \end{cases} \quad (1)$$

for every $j \in J$, then α_π^j is the smallest value $\alpha \geq 0$ for which $x^j(\alpha)$ satisfies the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. Observe that we define $\alpha_\pi^j = +\infty$ when the halfline $\{x^j(\alpha) : \alpha \geq 0\}$ does not intersect any of the hyperplanes $\pi^T x = \pi_0$ and $\pi^T x = \pi_0 + 1$. When $\alpha_\pi^j < +\infty$, the point $x^j(\alpha_\pi^j) = \bar{x} + \alpha_\pi^j r^j$ is

called an *intersection point* [1]. In Example 2, the points x^1 and x^2 are intersection points.

Given the numbers α_π^j for $j \in J$, a split cut associated with the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ can be defined as follows:

$$\sum_{j \in J} \frac{s_j}{\alpha_\pi^j} \geq 1. \quad (2)$$

Observe that for every $j \in J$ for which $\alpha_\pi^j < +\infty$, the point (x^j, s^j) defined by $x^j := x^j(\alpha_\pi^j)$, $s_j^j := \alpha_\pi^j$ and $s_k^j := 0$ for $k \in J \setminus \{j\}$ is in P and satisfies Equation (2) with equality. In other words, every intersection point gives a point in P that satisfies Equation (2) with equality.

Recall that the sets $P_\pi^1 := \{(x, s) \in P : \pi^T x \leq \pi_0\}$ and $P_\pi^2 := \{(x, s) \in P : \pi^T x \geq \pi_0 + 1\}$ give the points in P that satisfy the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. The validity of Equation (2) for the disjunctive hull $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ was proven by Balas [1]. In that paper Equation (2) was called the *intersection cut* due to the fact that the intersection points give points in P that satisfy Equation (2) with equality. The following lemma shows that, in fact, Equation (2) gives a complete description of the disjunctive hull:

Lemma 1. *Let $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ be a split disjunction. We have*

- (i) *If $\pi^T \bar{x} \notin [\pi_0, \pi_0 + 1]$, then $\text{Conv}(P_\pi^1 \cup P_\pi^2) = P$.*
- (ii) *If $\pi^T \bar{x} \in [\pi_0, \pi_0 + 1]$, then $\text{Conv}(P_\pi^1 \cup P_\pi^2) = \{(x, s) \in P : \text{satisfies Equation (2)}\}$.*

Lemma 1(i) shows that no split cut can be derived from a split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ that is satisfied by $\bar{x}$. Secondly, Lemma 1(ii) shows that inequality (2) is exactly the cut needed to describe the disjunctive hull when $\bar{x}$ violates the split disjunction.

Split Cuts from Bases and Split Cuts from Polyhedra

We now show how the results in the section titled “Split Cuts from Translates of Polyhedral Cones” can be used to derive split cuts from a basis of the LP relaxation of a MIP.

This basis can, for example, be an optimal basis for the LP relaxation. However, the results presented in this section apply to *any* basis of the LP relaxation. In this section we assume the LP relaxation of MIP is given by

$$P = \{x \in \mathbb{R}^n : Ax = b \text{ and } x \geq 0\},$$

where A is an $m \times n$ matrix, and b is an $m \times 1$ vector. Recall that the set $N := \{1, 2, \dots, n\}$ is used to index the coordinates of x , and that $N_I \subseteq N$ is used to index the variables that are integer constrained. We assume P has a basis; that is, we assume the rank of A is m . The j th column of A is denoted a_j .

Let $B \subseteq N$ denote a subset of the variables that define a basis of the LP relaxation; that is, suppose $|B| = m$ and that the vectors $a_j \in \mathbb{R}^m$ for $j \in B$ are linearly independent. Also let A_B denote the submatrix of A defined from the columns of A indexed by B , and let $J := N \setminus B$ index the nonbasic variables. Finally, let $\bar{x}(B) \in \mathbb{R}^n$ denote the basic solution corresponding to the basis B .

We now use the basis B to give a different representation of P . Firstly, by multiplying the equality system $Ax = b$ with the basis-inverse $(A_B)^{-1}$, we obtain

$$P = \{x \in \mathbb{R}^n : x_i + \sum_{j \in J} \bar{a}_{i,j} x_j = \bar{x}_i(B), \text{ for } i \in B \text{ and } x \geq 0\}, \quad (3)$$

where $\bar{a}_{i,j} \in \mathbb{R}^m$ for $j \in J$ is defined by $\bar{a}_{i,j} := (A_B)^{-1} a_j$. We next add the redundant equalities $x_j = x_j$ for $j \in J$ to the representation (3) of P . We can now write P in the following form:

$$P = \{x \in \mathbb{R}^n : \begin{aligned} x_i &= \bar{x}_i(B) - \sum_{j \in J} \bar{a}_{i,j} x_j, & \text{for } i \in B, \\ x_j &= x_j, & \text{for } j \in J, \\ x &\geq 0. \end{aligned} \quad (4)$$

Finally, by defining the vectors $r^j \in \mathbb{R}^n$ for $j \in J$

$$r_k^j := \begin{cases} -\bar{a}_{k,j} & \text{if } k \in B, \\ 1 & \text{if } k = j, \\ 0 & \text{otherwise,} \end{cases} \quad (5)$$

the representation (4) of P can be rewritten in the form

$$P = \left\{ x \in \mathbb{R}^n : x = \bar{x}(B) + \sum_{j \in J} r^j x_j \text{ and } x \geq 0 \right\}. \quad (6)$$

Observe that the vectors r^j for $j \in J$, and the basic solution $\bar{x}(B)$, are directly available from the simplex table corresponding to the basis B .

We now construct a relaxation of P corresponding to the basis B . If we skip the nonnegativity constraints on the basic variables x_i for $i \in B$, we obtain the following relaxation $P(B)$ of P :

$$\begin{aligned} P(B) &:= \{x \in \mathbb{R}^n : Ax = b \text{ and } x_j \geq 0 \text{ for } j \in J\} \\ &= \{x \in \mathbb{R}^n : x = \bar{x}(B) \\ &\quad + \sum_{j \in J} r^j x_j \text{ and } x_j \geq 0 \text{ for } j \in J\} \\ &= \bar{x}(B) + C(B), \end{aligned}$$

where $C(B)$ is the polyhedral cone generated by the vectors r^j for $j \in J$. Since $P \subseteq P(B)$, the valid inequalities for the mixed integer points in $P(B)$ are also valid inequalities for the mixed integer points in P . In particular, the split cuts that can be derived from $P(B)$ are also satisfied by the points in P_I .

We can therefore apply the results in the section titled “Split Cuts from Translates of Polyhedral Cones” to obtain valid split cuts for P_I from a split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ and $P(B)$. We now specialize the results in the section titled “Split Cuts from Translates of Polyhedral Cones” to the polyhedron $P(B)$.

Let $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ be an arbitrary split disjunction. First observe that Lemma 1(i) shows that if $\bar{x}(B)$ satisfies the split disjunction, then no split cut can be derived from $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ and $P(B)$. In the following, we therefore assume $\pi_0 < \pi^T \bar{x}(B) < \pi_0 + 1$. Let $\epsilon_\pi := \pi^T \bar{x}(B) - \pi_0$ denote the amount by which $\bar{x}(B)$ violates the first term of the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$.

As in the section titled “Split Cuts from Translates of Polyhedral Cones,” for every $j \in J$, we need to compute the smallest value $\alpha \geq 0$ for which $\bar{x}(B) + \alpha r^j$ satisfies the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. For every $j \in J$, let $\alpha_\pi^j(B)$ denote this value. Applying formula (1), we obtain that for every $j \in J$, the value

$$\alpha_\pi^j(B) := \begin{cases} \frac{\epsilon_\pi}{\sum_{i \in B} \pi_i \bar{a}_{i,j} - \pi_j} & \text{if } \pi_j - \sum_{i \in B} \pi_i \bar{a}_{i,j} < 0, \\ \frac{1 - \epsilon_\pi}{\pi_j - \sum_{i \in B} \pi_i \bar{a}_{i,j}} & \text{if } \pi_j - \sum_{i \in B} \pi_i \bar{a}_{i,j} > 0, \\ +\infty & \text{otherwise,} \end{cases} \quad (7)$$

is the smallest value of $\alpha \geq 0$ for which the point $\bar{x}(B) + \alpha r^j$ satisfies the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$. The split cut that can be derived from $P(B)$ and $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ is now given by

$$\sum_{j \in J} \frac{x_j}{\alpha_\pi^j(B)} \geq 1.$$

We now summarize what we have achieved in this section. Let $\mathcal{B}^*$ denote the set of *all* bases of P ; that is, let $\mathcal{B}^*$ be the set of m -subsets B of N such that the vectors a_j for $j \in B$ are linearly independent. Also, for every $B \in \mathcal{B}^*$ and split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$, let $P_\pi^1(B) := \{x \in P(B) : \pi^T x \leq \pi_0\}$ and $P_\pi^2(B) := \{x \in P(B) : \pi^T x \geq \pi_0 + 1\}$ denote the points in $P(B)$ that satisfy the split disjunction.

Lemma 1(ii) shows that, for any basis $B \in \mathcal{B}^*$ such that $\bar{x}(B)$ violates the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$, the disjunctive hull defined by $P(B)$ and $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ is given by

$$\begin{aligned} & \text{Conv}(P_\pi^1(B) \cup P_\pi^2(B)) \\ &= \left\{ x \in P(B) : \sum_{j \in J} \frac{x_j}{\alpha_\pi^j(B)} \geq 1 \right\}. \end{aligned}$$

In other words, the disjunctive hull defined by $P(B)$ and the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ is described by the split cut that can be obtained from $P(B)$ and the split disjunction. If $\bar{x}(B)$ satisfies the split disjunction,

then Lemma 1(i) shows that $\text{Conv}(P_\pi^1(B) \cup P_\pi^2(B)) = P(B)$; that is, the disjunctive hull defined by $P(B)$ and the split disjunction is given by $P(B)$, and no split cut can be derived.

Recall that $P_\pi^1 := \{x \in P : \pi^T x \leq \pi_0\}$ and $P_\pi^2 := \{x \in P : \pi^T x \geq \pi_0 + 1\}$ denote the points in P that satisfy the split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$, and that $\text{Conv}(P_\pi^1 \cup P_\pi^2)$ is the disjunctive hull defined by P and this split disjunction. A natural question is whether there are split cuts that can be obtained from P and a split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ which cannot be obtained from $P(B)$ and the split disjunction for some basis $B \in \mathcal{B}^*$. A negative answer to this question was given in Andersen *et al.* [4] by showing the formula

$$\text{Conv}(P_\pi^1 \cup P_\pi^2) = \cap_{B \in \mathcal{B}^*} \text{Conv}(P_\pi^1(B) \cup P_\pi^2(B)).$$

This formula shows that the disjunctive hull defined by P and a split disjunction $\pi^T x \leq \pi_0 \vee \pi^T x \geq \pi_0 + 1$ can be described by the split cuts that can be obtained from the split disjunction and bases B of P . We note that it was demonstrated in Andersen *et al.* [4] that infeasible bases are also needed for the formula to hold.

The formula also implies that the split closure can be rewritten as follows. Let $P_I(B) := \{x \in P(B) : x_j \text{ integer for all } j \in N_I\}$ denote the mixed integer points in $P(B)$, and let $\text{SC}(B)$ denote the split closure with reference to $P(B)$ and N_I . We have

$$\begin{aligned} \text{SC} &= \cap_{(\pi, \pi_0) \in \Pi} \text{Conv}(P_\pi^1 \cup P_\pi^2) \\ &= \cap_{(\pi, \pi_0) \in \Pi} \cap_{B \in \mathcal{B}^*} \text{Conv}(P_\pi^1(B) \cup P_\pi^2(B)) \\ &= \cap_{B \in \mathcal{B}^*} \cap_{(\pi, \pi_0) \in \Pi} \text{Conv}(P_\pi^1(B) \cup P_\pi^2(B)) \\ &= \cap_{B \in \mathcal{B}^*} \text{SC}(B). \end{aligned}$$

In other words, the split closure with reference to P and N_I is the intersection of the split closures with reference to the sets $P_I(B)$ and N_I over all bases B of P .

Strengthening Split Disjunctions

The idea of strengthening a cut $c^T x \geq c_0$ for P_I is to modify $c^T x \geq c_0$ to an inequality $\bar{c}^T x \geq \bar{c}_0$ that dominates $c^T x \geq c_0$ on P ; that is, to modify $c^T x \geq c_0$ to an inequality $\bar{c}^T x \geq \bar{c}_0$ that

cuts off more points of P . A procedure for strengthening split cuts was first presented by Balas and Jeroslow [12].

Let $B \in \mathcal{B}^*$ be an arbitrary basis of the LP relaxation of MIP, and let $(\pi, \pi_0) \in \Pi$ denote a split disjunction that is violated by $\bar{x}(B)$. We now show how to construct a split disjunction $(\pi', \pi'_0) \in \Pi$ such that the split cut derived from $P(B)$ and (π', π'_0) dominates the split cut derived from $P(B)$ and (π, π_0) .

The procedure we present only modifies coordinates of π corresponding to nonbasic and integer-constrained variables. Let $J_I := J \cap N_I$ index those coordinates, and let $k \in J_I$ be arbitrary. For simplicity, let $\bar{a}^k(\pi) := \sum_{i \in B} \pi_i \bar{a}_{i,k}$.

By using Equation (7) of the section titled “Split Cuts from Bases and Split Cuts from Polyhedra,” the coefficient on x_k in the split cut defined by $P(B)$ and (π, π_0) is given by $\frac{1}{\alpha_\pi^k(B)}$, where

$$\alpha_\pi^k(B) := \begin{cases} \frac{\epsilon_\pi}{\bar{a}^k(\pi) - \pi_k} & \text{if } \pi_k - \bar{a}^k(\pi) < 0, \\ \frac{1 - \epsilon_\pi}{\pi_k - \bar{a}^k(\pi)} & \text{if } \pi_k - \bar{a}^k(\pi) > 0, \\ +\infty & \text{otherwise.} \end{cases} \quad (8)$$

Observe that the value π_k in the split disjunction (π, π_0) is not involved in the formula for $\epsilon_\pi = \sum_{i \in B} \pi_i \bar{x}_i(B) - \pi_0$. Hence the violation of the split disjunction is not changed if we change π_k to another integer. Furthermore, π_k is not involved in the formula for $\alpha_\pi^j(B)$ for any $j \in J \setminus \{k\}$.

It follows that we can choose a new value π'_k for π_k so as to minimize the coefficient $\frac{1}{\alpha_{\pi'}^k(B)}$ on x_k without changing the coefficients on the other nonbasic variables in the resulting split cut.

It is easy to see that the optimal value π'_k for π_k is either $\pi'_k = \lfloor \bar{a}^k(\pi) \rfloor$ or $\pi'_k = \lceil \bar{a}^k(\pi) \rceil$. If we choose $\pi'_k = \lfloor \bar{a}^k(\pi) \rfloor$, then the new value of $\alpha_{\pi'}^k(B)$ will be $\frac{\epsilon_\pi}{\bar{a}^k(\pi) - \lfloor \bar{a}^k(\pi) \rfloor}$ and if we choose $\pi'_k = \lceil \bar{a}^k(\pi) \rceil$, the new value of $\alpha_{\pi'}^k(B)$ will be $\frac{1 - \epsilon_\pi}{\lceil \bar{a}^k(\pi) \rceil - \bar{a}^k(\pi)}$. Since we would like to make the coefficient $\frac{1}{\alpha_{\pi'}^k(B)}$ on x_k as small as possible, it is best to choose $\pi'_k = \lceil \bar{a}^k(\pi) \rceil$ if $\frac{1 - \epsilon_\pi}{\lceil \bar{a}^k(\pi) \rceil - \bar{a}^k(\pi)} > \frac{\epsilon_\pi}{\bar{a}^k(\pi) - \lfloor \bar{a}^k(\pi) \rfloor} \iff \epsilon_\pi < \bar{a}^k(\pi) - \lfloor \bar{a}^k(\pi) \rfloor$. Otherwise, it is best to choose $\pi'_k = \lfloor \bar{a}^k(\pi) \rfloor$.

We therefore have the following lemma which shows how to obtain a split disjunction $(\pi', \pi'_0) \in \Pi$ from (π, π_0) such that the split cut derived from (π', π'_0) and $P(B)$ dominates the split cut derived from (π, π_0) and $P(B)$.

Lemma 2. *Let $B \in \mathcal{B}^*$ be a basis of P and let $(\pi, \pi_0) \in \Pi$ be a split disjunction violated by $\bar{x}(B)$. Define the split disjunction $(\pi', \pi'_0) \in \Pi$ by $\pi'_0 := \pi_0$ and*

$$\pi'_j := \begin{cases} \pi_j & \text{if } j \in N \setminus J_I, \\ \lfloor \bar{a}^j(\pi) \rfloor & \text{if } j \in J_I \text{ and } \bar{a}^j(\pi) \\ & - \lfloor \bar{a}^j(\pi) \rfloor \leq \epsilon_\pi, \\ \lceil \bar{a}^j(\pi) \rceil & \text{if } j \in J_I \text{ and } \bar{a}^j(\pi) \\ & - \lfloor \bar{a}^j(\pi) \rfloor > \epsilon_\pi. \end{cases} \quad (9)$$

Then, the split cut obtained from (π', π'_0) and $P(B)$ dominates the split cut obtained from (π, π_0) and $P(B)$.

Mixed Integer Gomory Cuts from Rows of the Simplex Table

Given a row of a simplex table, a mixed integer Gomory cut [13] can be derived. Throughout this section $B \in \mathcal{B}^*$ denotes an arbitrary basis of the LP relaxation. Consider the row of the simplex table where the variable x_i , $i \in B$, is basic:

$$x_i + \sum_{j \in J} \bar{a}_{i,j} x_j = \bar{x}_i(B).$$

Assume $\bar{x}_i(B)$ is fractional. Define $f_0 := \bar{x}_i(B) - \lfloor \bar{x}_i(B) \rfloor$ and $f_j := \bar{a}_{i,j} - \lfloor \bar{a}_{i,j} \rfloor$ for the nonbasic and integer-constrained variables $j \in J_I$. Gomory showed that the following inequality is satisfied by the mixed integer points in P_I :

$$\sum_{j \in J_I: f_j \leq f_0} \frac{f_j}{f_0} x_j + \sum_{j \in J_I: f_j > f_0} \frac{1-f_j}{1-f_0} x_j + \sum_{j \in J \setminus J_I: \bar{a}_{i,j} \geq 0} \frac{\bar{a}_{i,j}}{f_0} x_j - \sum_{j \in J \setminus J_I: \bar{a}_{i,j} < 0} \frac{\bar{a}_{i,j}}{1-f_0} x_j \geq 1. \quad (10)$$

We will derive inequality (10) as a split cut in two steps. First consider the split disjunction $(\pi, \pi_0) \in \Pi$ defined by $\pi_0 := \lfloor \bar{x}_i(B) \rfloor$ and $\pi = e^i$, where e^i denotes the i^{th} unit vector.

Observe that $\epsilon_\pi = f_0$. Applying formula (7) of the section titled “Split Cuts from Bases and Split Cuts from Polyhedra,” we obtain the following split cut from $P(B)$ and the split disjunction (π, π_0) :

$$\sum_{j \in J: \bar{a}_{i,j} > 0} \frac{\bar{a}_{i,j}}{f_0} x_j - \sum_{j \in J: \bar{a}_{i,j} \geq 0} \frac{\bar{a}_{i,j}}{1-f_0} x_j \geq 1. \quad (11)$$

Inequality (11) is also known as *Gomory’s fractional cut*. The second step is to apply Lemma 2 to strengthen the split disjunction (π, π_0) . Formula (9) now gives the following strengthened split disjunction (π', π'_0) of (π, π_0) :

$$\pi'_j = \begin{cases} \pi_j & \text{if } j \in N \setminus J_I, \\ \lfloor \bar{a}_{i,j} \rfloor & \text{if } j \in J_I \text{ and } \bar{a}_{i,j} - \lfloor \bar{a}_{i,j} \rfloor \leq f_0, \\ \lceil \bar{a}_{i,j} \rceil & \text{if } j \in J_I \text{ and } \bar{a}_{i,j} - \lfloor \bar{a}_{i,j} \rfloor > f_0. \end{cases}$$

Computing the split cut associated with (π', π'_0) and $P(B)$ then gives the mixed integer Gomory cut (Eq. 10).

COMPUTATIONAL RESULTS ON THE SPLIT CLOSURE

Balas and Saxena [10] optimized over the split closure for a number well-known test problems. Specifically, a MIP was considered, and the best solution in the split closure was computed. We now present their approach, and some of the computational results that were obtained. In this section, we assume the LP relaxation P of P_I is of the form $P = \{x \in \mathbb{R}^n : Ax \geq b\}$.

In order to optimize over the split closure, the *separation problem* for the split closure needs to be solved. This separation problem receives as input a (current) point $\bar{x} \in P$, and addresses the question of whether or not there exists a split cut that is violated by $\bar{x}$. If such a split cut exists, this split cut must be returned.

Let $\bar{x} \in P$ denote a point that must be separated from SC, if possible, and let $\bar{s} := A\bar{x} - b$ denote the corresponding values of the surplus variables. Balas and Saxena formulated

the separation problem for the split closure with reference to P and N_I as the following parametric mixed integer linear program (PMILP):

$$\begin{aligned}
& \min z(\theta) := (1 - \theta)u^T \bar{s} + \theta v^T \bar{s} - \theta(1 - \theta) \\
& \text{s.t.} \\
& (u - v)^T A - \pi = 0, \\
& (v - u)^T b + \pi_0 = \theta - 1, \\
& u, v \geq 0, \\
& (\pi, \pi_0) \in \Pi, \\
& 0 \leq \theta \leq 1.
\end{aligned}$$

Balas and Saxena showed that solving PMILP solves the separation problem for the point $\bar{x}$ and the split closure with reference to P and N_I . Specifically, it was shown that the point $\bar{x}$ belongs to the split closure with reference to P and N_I if and only if the optimal objective value to PMILP is nonnegative. If the optimal objective of PMILP is negative, then an optimal solution $(u^*, v^*, \pi^*, \pi_0^*, \theta^*)$ to PMILP gives a split cut $\alpha^T x \geq \beta$ defined by

$$\begin{aligned}
\alpha &= (u^*)^T A - \theta^* \pi^* \text{ and} \\
\beta &= (u^*)^T b - \theta^* \pi_0^*,
\end{aligned}$$

which is violated by $\bar{x}$.

Observe that PMILP is a nonlinear mixed integer program. However, also observe that if the variable $\theta \in [0, 1]$ is fixed to a specific value, then the remaining problem is a mixed integer linear program. This observation can therefore be exploited by discretizing the interval $[0, 1]$ and only solve PMILP for

Table 2. Summary of Results for Pure Integer Instances

Total Number of Pure Integer Instances	23
Average % gap closed by split closure	72.47%
98–100% gap closed	9
75–98% gap closed	4
25–75% gap closed	6
< 25% gap closed	4

a finite set of carefully chosen values of $\theta \in [0, 1]$.

The above observation is then used by Balas and Saxena to design a cutting-plane algorithm for optimizing over the split closure with reference to P and N_I . First, the LP relaxation of MIP is solved, and an optimal solution $\bar{x}$ is obtained. The separation problem PMILP is then solved for $\bar{x}$ and a number of selected values of $\theta \in [0, 1]$. If a violated split cut is found, the cut is added to the (current) LP relaxation, the problem is reoptimized and a new point $\bar{x}$ is obtained to be separated. This procedure is then iterated. The cutting-plane algorithm terminates when it is concluded that enough values of $\theta \in [0, 1]$ have been tested without finding a violated split cut. Observe that although a cutting-plane is added in every iteration, this cut is *not* included in the formulation of the separation problem PMILP; that is, the separation problem PMILP is always formulated in terms of the original constraints $Ax \geq b$.

Balas and Saxena measures the performance of the above algorithm by the amount of integrality gap that is closed. Table 1 and Table 2 below are from Balas and Saxena [10], and they give a short summary of the performance of split cuts. There are a total of 61 test problems. Table 1 gives results for the mixed integer instances, and Table 2 gives results for the pure integer instances (when there are no continuous variables). As can be seen from these tables, the split cuts close a substantial amount of the integrality gap on most problems. Furthermore, in Balas and Saxena [10] and Dash *et al.* [5], the split closure is compared with other classes of cutting-planes, and it is concluded that split cuts most often close substantially more of the integrality gap.

Table 1. Summary of Results for Mixed Integer Instances

Total Number of Mixed Integer Instances	38
Average % gap closed by split closure	72.78%
98–100% gap closed	15
75–98% gap closed	10
25–75% gap closed	7
< 25% gap closed	6

SPREADSHEET MODELING FOR OPERATIONS RESEARCH PRACTICE

THOMAS GROSSMAN
University of San Francisco,
San Francisco, California,
USA

This article presents the essential information for operations research practitioners to make effective use of spreadsheets, with particular attention to issues that are important to success but not widely understood.

Spreadsheets have been an important platform for analysis ever since VisiCalc launched in 1979. Spreadsheets put the power of mathematical modeling and computer programming into the hands of anyone with a PC. Microsoft Excel is as much a part of the modern office as a desk, and spreadsheets have a high degree of acceptance among managers. Empirical research shows many examples where spreadsheets are used for managerial decision making or are otherwise essential to finance, operations, general business, and science [1–4].

Spreadsheets are a valuable resource in the practitioner's toolbox. The spreadsheet is a flexible fourth-generation programming language with high acceptance by consulting clients, endowed with remarkable power and flexibility for operations research techniques. Practitioners can enhance their effectiveness by integrating the spreadsheet into their practice

EXAMPLES OF HIGH IMPACT OPERATIONS RESEARCH USING SPREADSHEETS

Here are some examples of spreadsheets having an impact on operations research practice.

Oggier *et al.* [5] explain how Nestlé deployed operations research to end users around the world. They developed, deployed, and integrated into their global business

practices sensitivity analysis, forecasting, simulation, and optimization. Distributed analysts use them for evaluating the economic profitability of Nestlé's projects and more generally evaluating the value of the Nestlé group and its many businesses.

A special issue of Interfaces [6] contains 12 papers highlighting the rich usage of spreadsheets in operations research practice. Farasyn *et al.* [7] describe how Procter & Gamble (P&G) used spreadsheet models across the company to determine optimal inventory levels for required customer service levels, subject to the characteristics and constraints of particular supply chains. The models have contributed to inventory reductions exceeding \$350 million and significant intangible benefits to P&G. Because the spreadsheet models are easy to use and share, they became the standard tool for inventory setting at P&G and are used by hundreds of supply chain planners worldwide.

Olavson and Fry [8] discuss their experiences in building and applying spreadsheet-based decision-support tools. Using examples from Hewlett-Packard (HP) in forecasting, planning, procurement, and product management, they discuss lessons learned for creating reusable spreadsheet tools to support fact-based decision making, and using spreadsheets as the front- and back-end user interface for models coded in a procedural language. This article is notable for providing a high level road map for approaching operations research-driven change projects (independent of spreadsheets) with options ranging from “no analytics” because the organization is not ready, through to “transferable tool.”

Amaral and Kuettner [9] review spreadsheet techniques and approaches that they used to analyze supply chains at HP and to manage spreadsheet limitations. They discuss how they employed many of Excel's advanced capabilities while minimizing unnecessary complexity.

Pasupathy and Medina-Borja [10] describe the use of data envelopment analysis to make resource-allocation recommendations to help American Red Cross managers evaluate the performance of different chapters. They integrate Microsoft Excel, Premium Solver, Visual Basic for Applications, and Microsoft Access to formulate, automatically program, and solve 4000 different linear-programming models.

IMPLEMENTING OPERATIONS RESEARCH MODELS IN A SPREADSHEET

The spreadsheet is suitable for programming high quality operations research models. As discussed later, the spreadsheet can be tolerant of poor programming practices that work initially but prove unmaintainable over time. Therefore, it is incumbent on the operations research practitioner to perform a spreadsheet programming task with the same rigor and diligence as with a traditional language such as C#. The operations research programmer will benefit from understanding the characteristics of the spreadsheet programming language, the principles of “spreadsheet engineering,” and the findings of research on spreadsheet errors.

The Spreadsheet as a Programming Language

This section is based on Grossman *et al.* [4]. Operations research practitioners select a traditional programming language (e.g., FORTRAN, C#, Java) based on its characteristic strengths and weaknesses for a given task. Let us examine the characteristics of the dominant spreadsheet language, Microsoft Excel.

First, Excel is a “fourth-generation language” (4GL). Second, Excel is in the class of “rapid development languages” (RDLs). Third, Excel functions as an “integrated development environment” (IDE).

A 4GL is a nonprocedural programming language with natural language-like features that can be employed directly by less skilled programmers, with a simple interface. Analysts can use a 4GL, such as Excel, to develop computer applications more rapidly than conventional programming languages and enjoy

dramatic boosts in productivity. In addition, the spreadsheet has a higher level of abstraction than do third-generation languages, with automatic definition of variables by grid location, automatic variable typing, and no concept of registers or storage locations; indeed the underlying hardware is invisible.

The spreadsheet is a member of a class of programming languages called *rapid-development languages* that yield faster development than traditional languages. Using the “function point” measure of the work accomplished by a computer program, spreadsheets require on average only six statements to implement a function point that would require 30 statements in Visual Basic, 50 statements in C++, or 110 statements in FORTRAN, and hence “spreadsheets boost productivity through the roof” [11].

The spreadsheet functions as an IDE, which is a software tool that helps programmers create applications by simplifying or automating programming tasks. The spreadsheet provides a seamlessly integrated source code editor and interpreter, and powerful report creation and printing capabilities. The spreadsheet itself provides a simple graphical user interface (GUI), and Excel’s Forms toolbar provides convenient tools for building more advanced GUI features that allow spreadsheet application software to be developed. It is notable that the spreadsheet grants the programmer real-time observation of programming statement results; this powerful feature of the spreadsheet computer programming language is typically not available in other languages, and provides much of the functionality of a traditional debugger. Excel also provides helpful productivity tools such as Trace Precedents/Dependents, Display Formulas, R1C1 cell referencing, as well as traditional tools such as Watch Window and Evaluate Formula.

In the final analysis, the spreadsheet programming language is “highly functional, extendible, easy to integrate, and scalable” [12].

Spreadsheet Engineering

Professional programmers understand the necessity of employing a rigorous software engineering methodology when implementing an operations research model in any programming language. Spreadsheets are no different. The principles and practices of “spreadsheet engineering”—software engineering for spreadsheets—are necessary to write effective, maintainable code in a spreadsheet programming language. However, because the spreadsheet is an RDL, it is tolerant of poor coding practices [11]; hence spreadsheet programs are accommodating of poorly structured, unmaintainable code. This does not mean that the spreadsheet is a poor programming language, but rather that the programmer must be diligent to employ good practices.

Several operations research organizations have proprietary spreadsheet engineering methodologies. These are rigorous, refined, documented, and vital to their success. However, published spreadsheet engineering methodologies are underdeveloped relative to methodologies for traditional languages. The operations research professional who writes spreadsheet software is well-advised to familiarize himself/herself with the existing spreadsheet engineering methodologies, and should be aware that the general principles of traditional software engineering apply to writing programs in a spreadsheet language.

The domain of large-scale spreadsheet financial planning models has several sophisticated methodologies ([13, 14], and Operis in [15]), which are compared in [16]. There have been a few sets of detailed spreadsheet engineering recommendations for creating more general spreadsheet models, especially financial models. The most complete are book-length treatments by Read and Batson [17] and Tennent and Friend [18]. Valuable contributions can be found in Chapter 3 of [19] and [20].

A particular risk when using a spreadsheet language is the failure to discard a prototype model implementation. An initial proof-of-concept model programmed in any language is normally a poor foundation for further programming effort. Just as in a traditional language, it is essential to discard a

prototype spreadsheet, and start over with a structured design, similar to a painter who discards an initial sketch and uses a fresh canvas for the final work.

Research Findings on Spreadsheet Errors

A spreadsheet containing cell formulas is a computer program, and all computer programs are susceptible to errors. A corpus of spreadsheet errors is available [21]. Several scoping-level studies (summarized in [22, 23]) suggest that spreadsheets are excessively susceptible to errors. This prompted more rigorous follow-on research [24–27] which finds that the definition of errors is problematic; past studies are insufficiently documented and suspected; careful auditing identifies many potential errors, many of which cause no numerical impact; and some documented errors are large. Most important, they find that some organizations seem to be able to build error-free spreadsheets.

There is evidence that professional programmers use spreadsheets at a high level of accuracy [4] including a massive (70 MB) spreadsheet that has been demonstrated to be error-free. This, plus the many examples of successful spreadsheet application software belie any special error risk when spreadsheets are written by people with programming skill.

The professional literature on programming [28] suggests that the distinction between unskilled “amateur” programmers trumps any special error vulnerabilities of the spreadsheet compared to other languages. In Weinberg’s nomenclature, amateur programmers have domain skill but not programming skill, and generally write bad code in whatever language they use. In contrast, professional programmers have programming skill independent of any domain skill, and generally write good code.

Hence, poor programmers are likely to write poor spreadsheets, and good programmers are likely to write good spreadsheets. This is consistent with the findings of the spreadsheet error literature. The hypothesis that spreadsheets are unusually error-prone or unsafe is at best unproven.

As a practical matter, an operations research team that has the sophistication

to write quality software in a procedural language can undoubtedly write quality software in a spreadsheet language provided they approach the task with equivalent diligence.

FOUR APPROACHES TO USING SPREADSHEETS IN OPERATIONS RESEARCH PRACTICE

There are four approaches to using spreadsheets for operations research practice: Direct programming, VBA to generate spreadsheet cell formulas, Direct VBA, and Spreadsheet for I/O. (Note: VBA, or “Visual Basic for Applications,” is a popular programming language that is bundled free with Excel. VBA is a simplified version of the programming language Visual Basic that is used routinely by professional programmers in many disciplines. VBA has strong integration with the Excel spreadsheet.)

The Direct programming approach is writing spreadsheet cell formulas in the usual way. Direct programming is by far the most common approach. Amaral and Kuettner [9] show how some lesser-known Excel features can be used to enhance the user interface and program flexible scenarios.

The VBA to generate spreadsheet cell formulas approach enables the programmer to surmount the limitations of direct programming. Direct programming can be very challenging for large-scale models, and models with a high degree of dimensionality. Although it is easy to use the spreadsheet Copy-Paste and Fill features to create cell formulas, it becomes impractical when there are variations in formulas that must be typed by hand. To solve this problem, the analyst can use VBA to populate a spreadsheet with cell formulas; in essence, one writes a program to write a program. Details can be found in [29]. This approach is powerful and surprisingly straightforward.

The Direct VBA approach requires coding the model in VBA, and using the spreadsheet proper primarily for data management. In this approach, the spreadsheet itself is relatively simple, and the complexity of the model is handled behind the scenes by VBA code. VBA can make calls to sophisticated

operations research algorithms that are custom-written or provided by third-party vendors. Pasupathy and Medina-Borja [10] use a spreadsheet and VBA to automate the creation and solution of thousands of linear programs.

The Spreadsheet for I/O approach requires the use of traditional operations research software, such as a matrix generator coded in a procedural language, or a modeling language such as GAMS or AMPL. Data is pulled in from a spreadsheet and results pushed out into a spreadsheet.

Regardless of the approach, the operations research practitioner can take advantage of Excel’s effective reporting and graphing capabilities, and the widespread availability of Excel on desktops around the globe.

SPREADSHEET TOOLS FOR OPERATIONS RESEARCH

More information on these products can be found in [30] and a compendium [31]. Operations research algorithms are provided in spreadsheets via third party “add-ins.” Spreadsheet add-ins are products that add capability to the spreadsheet. Add-ins can provide new features accessed through menus, new functions, or be precoded modules in the form of templates. There is a sizable ecosystem of commercial add-ins for operations research and other analytic needs. Add-ins for operations research fall into three distinct groups: model-driven analysis (including Monte Carlo simulation and optimization), statistics and data-driven analysis, and business function-specific analysis. Operations research practitioners should also be aware of certain spreadsheet productivity tools.

Productivity and Spreadsheet Development Tools

There are add-ins to aid spreadsheet development including error checking, spreadsheet comparison tools, automation, security, version control, and more [32].

Model Handoff to Clients and Spreadsheet Application Software

Operations research practitioners sometimes need to transfer a model to a client, or to convert a model into a standalone application. With a spreadsheet, model transfer is challenging because unless appropriate steps are taken, the source code can be modified by the user with unpredictable results. This issue is discussed in [9, 33].

There exist tools to remove access to the source code before deployment to users, by converting a spreadsheet into a standalone application (i.e., an executable file) or web-based HTML page. One can also use Excel features to convert a spreadsheet into an add-in [34].

Model-Driven Analysis

Model-driven analysis is the application of an analytical technique to a spreadsheet model to obtain insight or decision guidance. There is a tutorial paper on performing sensitivity analysis in native Excel [35], and on scenario analysis in native Excel and integrating it with optimization and simulation [36]. There are several commercial tools for sensitivity analysis that quickly compute and chart the effect of changing an input on a designated output, or generate a Tornado Chart, including SensIt, TopRank, and Risk Solver Platform, and the academic tool Sensitivity ToolKit [37].

There are tools that perform iterative search, extending the Goal Seek feature of Excel that searches on a model input to obtain a specified value of a model output. These handle multiple goal seeks at once and can remember and repeat them. They include Spreadsheet Goal Seeker, and multicell Goal Seeker [38].

There are several commercial add-ins for building and computing decision trees, including TreePlan, PrecisionTree, and Risk Solver Platform [39].

Monte Carlo Simulation. There are several feature-rich commercial add-ins for Monte Carlo simulation. In addition to Oracle's Crystal Ball and Palisade's @Risk, recent entrants include Vose Software's

ModelRisk and Frontline Systems' Analytic Solver Platform with innovative "simulation optimization" capability [40].

Optimization. Optimization add-ins to Excel are the mostly highly developed, and are distinctive for their power. Optimization in a spreadsheet can be done using Excel's built-in Solver feature. Befitting a free product made available to the mass market, the built-in Solver is accessible to users with little or no operations research training, has restrictions on model size, and provides a limited feature set. The built-in Solver has proven valuable for countless users, is employed routinely in some business processes, and has introduced the power of optimization to a mass audience.

Operations research practitioners with more demanding requirements will want to utilize one of the high performance commercial optimization add-ins that are available [41]. The leading commercial products are the Premium Solver and Analytic Solver Platform by Frontline Systems (the vendor of the built-in Solver), and What's Best! by Lindo Systems. Spreadsheet solvers can handle problems of large scale and complexity. These add-ins can integrate with third-party, world-class optimization tools such as CPLEX and GUROBI, and have the ability to extract the underlying optimization mode out of the spreadsheet, feed it to an external algorithm that runs independent of the spreadsheet, and then populate the spreadsheet with the optimal solution.

The level of performance of commercial spreadsheet optimization add-ins can be very high. For example (Straver and Fylstra, personal communication, June 14, 2012) describe the use of the Analytic Solver Platform add-in to Excel using the GUROBI solver, to solve to optimality a real-world linear programming model with 2.4 million decision variables and 50,000 constraints in 6 min and 52 s using a \$1000 personal computer. This includes 1:00 min to parse the spreadsheet model, 5:20 min for GUROBI to set it up, and 24 s for GUROBI to optimize it.

Spreadsheet optimization is suitable for routine use. For example, a utility company has a spreadsheet linear program with

250,000 decision variables that is optimized on a regular basis (Straver and Fylstra, personal communication, June 14, 2012).

There are commercial add-ins for metaheuristics, including Analytic Solver Platform and Evolver. Parametric optimization can be performed using the commercial product Analytic Solver Platform, and also academic products Sensitivity ToolKit, and SolverTable [42].

Spreadsheet Design for Optimization. For most operations research techniques, an add-in has obvious spreadsheet design requirements (e.g., decision tree add-ins) or can handle arbitrary spreadsheet design (e.g., simulation add-ins). In contrast, optimization models are sensitive to spreadsheet design. When constructing a spreadsheet model that will be subject to optimization, it is important to code the model so as to preserve linearity (which is challenging to verify in a spreadsheet and hence must be built-in at design time), and enable easy identification of constraints to the optimization add-in. Guidelines and examples for using spreadsheets for optimization can be found in [19, 43–45].

Statistics and Data-Driven Analysis

Statistics and data-driven analysis are tools that perform statistics and business intelligence functions, including forecasting. Excel has a free statistics add-in called the *Analysis ToolPak* that in older releases has exhibited quality problems and lost the confidence of the statistics community; these issues have largely been addressed. In addition, there are many commercial statistics add-ins available at a variety of price points, including StatTools, Lumenaut Statistics, and Analyse-it [46].

Commercial tools for spreadsheet data mining include XLMiner, Analytic Solver Platform, and NeuroXL [47].

Spreadsheet time-series forecasting has around a dozen add-in products. These generate time-series forecasts using smoothing, regression, and neural network approaches. They include XLMiner, ForecastX Wizard, and PeerForecaster [48].

Business Function-Specific Analysis

There are several commercial add-ins designed for specific functional areas of business. In finance, there are add-ins for pricing various types of derivatives, to support trading decisions (with integration to brokers), and a tool for automatic data feeds. There is a tool for spreadsheet marketing engineering, templates for spreadsheet marketing plans, and a spreadsheet advertising keyword pricing tool. There are spreadsheet tools for Six Sigma greenbelts, for statistical quality control, and even spreadsheet tools intended for use on the factory floor [31].

The Queueing ToolPak add-in [49] offers add-in Excel functions that allow the practitioner to easily program queueing theory formulas directly in a spreadsheet.

STAKEHOLDER PARTICIPATION

ROBERT L. HEATH
School of Communication,
University of Houston,
Houston, Texas

Consideration of stakeholder and stakeholder participation is as old as discussions of society and practices of governance. In the past forty years, however, the term has become widely and sometimes loosely used in academic and professional literature, and even in media coverage and popular jargon. It is widely discussed in management, public relations, issues management, marketing, business ethics, governance, and even product/service advertising. References to triple bottom line thinking can suggest some very heavy lifting to engage with various stakeholders to mutual benefit or serve as mere platitude that can be distorted by market positioning.

Reflecting the seriousness of stakeholder engagement, Renn *et al.* [1] cautioned, “Without public involvement, environmental policies are doomed to fail” (p. xiii). Concerns about sustainability, corporate social responsibility, social marketing, and community relations make stakeholder participation an important topic for management and operations. The topic requires theoretical examination, monitoring processes, understanding of negotiation and collaborative decision making, as well as examination of the ethics of community engagement.

Interest in stakeholders takes a descriptive/pragmatic tack as well as a normative approach based on the ethics of citizenship. The post-World War II era, especially during the civil rights and anti-Vietnam war battles, moved a peripheral topic into prominence. Riding this wave, Freeman [2] helped popularize stakeholder theory and participation as a driver of strategic management. Topics such as decision analysis, control in the face of uncertainty, and risk management and communication have grown variously

from the logic he and others articulated. Looking at stakeholders from a private sector perspective, he advised, “A situation where a solution to a stakeholder problem is imposed by a government agency or the courts must be seen as a managerial failure” (pp. 74–75). Thus, he reasoned, “Managers in organizations with high Stakeholder Management Capability think in ‘stakeholder-serving’ terms” (p. 80). Among the many reports emphasizing the ethical (as risk democracy) and functional value of stakeholder participation were the National Research Council’s *Improving Risk Communication* (1989), *Understanding Risk* (1996), and *Decision Making for the Environment* (2005). Similarly relevant is the logic of Kahneman *et al.* [3] that judgment often is made under uncertainty which depends on individual reference points, varied willingness to risk, and sense of utilities to be gained or lost.

STAKEHOLDER LOGIC

Stakeholder theory addresses rights and obligations (both inside and outside of an organization regardless of whether it is for profit, nonprofit, or governmental) as power resources applied by competing interests. The topic is inseparable from related considerations of efficiency, power, risk, and control. Competing interests and conflicting issue positions are fundamental to stakeholder theory. Interest is best conceptualized as something desired to be gained or lost—something that can be risked or is at risk. Conflict results as power is wielded by each person’s or any group’s ability and willingness to use resources to maximize its outcomes even if that means (and in conflict it can) diminishing other groups’ or persons’ ability to achieve their goals.

What then is the rationale for the popularity of the term, and even the argument that there is a stakeholder theory? As de Bussy [4,5] observed, “The theory raises

a highly contentious question: in whose interest should a business corporation or other type of organization be run?" (p. 4815). One answer is that the interest served is that of the organization (as a collective of many interests). It would presume that the organization through various power resources makes the stakeholder dependent on it for serving the interest of the stakeholder. Another view suggests that the stakeholder and the organization have mutual, and even aligned, interests, in fact mutually beneficial interests and objectives.

A pragmatic and even cybernetic logic reasons that each organization depends on the stakeholders who hold resources that the organization needs to achieve its mission and vision. Pragmatically, the focal organization might be a dominant force in the relationship, the stakeholder might be dominant, or the relationship might be mutually beneficial. In fact, the matter may often be more a matter of "grey" rather than any one of the three options purely applied.

A stake is something of value (tangible or intangible, material or symbolic—or both) that one organization or entity holds that another wants or needs: A risk of gain or loss. Mitchell *et al.* [6] defined stake as "something that can be lost. The use of risk to denote stake appears to be a way to narrow the stakeholder field to those with legitimate claims, regardless of their power to influence the firm or the legitimacy of their relationship to the firm" [7, 8]. Wages or salary, by this definition, is a stake, but so is trust. Labor is a resource, as is wage or salary. The quality of each product is a stake. A buyer needs more stakes to buy a higher quality item—all other factors being the same. A coal mining company needs stakes held (application of regulatory standards) by regulators and legislators (environmental protection standards translated into regulation) as well as stakes of employee goodwill.

Stakeholders and stakeholders are bound to one another by relationships defined by exchange processes and the meaning that defines the stakes and those processes. Stakeholders have stakes that under various conditions they grant or hold. For instance, workers hold stakes (their time, skill, and

effort) that they can grant to or hold from various companies that need labor; employment contracts, labor relations, and marketplace conditions define such exchange. Stakes (salary, wages, and other benefits) held by the company can be granted to workers in this exchange. Workers are stakeholders of wages/salaries and benefits—as well as working conditions, such as safety. Safety may be assured by the employer or required by legislation and regulation. The rationale for resource dependency is that each definable entity is variously a stakeholder and a stakeholder who have interests more or less aligned.

Freeman and Gilbert [9] advised the following implications of effective understanding and engagement with stakeholders: "Corporate strategy must reflect an understanding of the values of organizational members and stakeholders." Such understanding can and must inform "the ethical nature of strategic choice" (p. 7).

Each organization, a business for instance, has multiple stakeholders (and stakeholders), on which they are likely to be variously dependent and interdependent through complex stakeholder/stakeholder networks. Thus, for instance, the workers who seek the stakes of safe working conditions hold votes that legislators need. Thus, the votes of the workers are exchanged for the legislative position of the legislators who hold the stake as to whether the regulation produces (or does not) a safe working environment. This notion of multiple stakes, multiple stakeholders (and the reciprocation) of stakeholders is the essence of stakeholder participation. Stakeholder theory and participation best practices center on rights, obligations, legitimacy, reputation, power resources, and the quality of relationships, particularly as interests are aligned badly or well. As a consequence, strategic management relies on stakeholder/holding and granting; strategic participation depends on knowing who the stakeholders are, what stakes they hold, and their willingness and ability to use them as resources to add value in efforts to align interests and achieve objectives.

MONITORING AS STRATEGIC MANAGEMENT

The strategic management challenge is to identify those persons, groups, and organizations who can affect the organization and who are affected by it in ways that pose opportunity or peril. Strategic management depends on effective stakeholder monitoring: Identifying stakeholders, knowing their interests and relationships (dependence, interdependence, and independence) with the organization and other stakeholders, and their issues positions. Monitoring must be guided by vigilant regard for stakeholders' willingness and ability to participate and to grant or withhold stakes the organizations wants and needs. In such matters, two strategic management alternatives are salient: risk analysis and decision analysis. "A decision analysis can include a risk analysis component, and the design of a risk management plan may require decision analysis support" [10].

The years following World War II witnessed increased activism that peaked during the 1960s and 1970s. During this era, issues management and related disciplines developed to propose systems for monitoring and engaging stakeholders. Organizations developed means for scanning, identifying, tracking, interpreting, and analyzing issues and their advocates [7]. Strategic management, operations, decisions about corporate social responsibility, marketing especially social marketing, and public relations developed functional and ethical responses to critics.

Mitchell *et al.* [6] aided efforts to identify and understand stakeholders by addressing not only who or what really counts, but also the "maddening variety of signals on how questions of stakeholder identification might be answered" (p. 853). They addressed ways of knowing "which groups are stakeholders deserving or requiring management attention, and which are not" (p. 854). They reasoned, "Persons, groups, neighborhoods, organizations, institutions, societies, and even the natural environment are generally thought to qualify as actual or potential stakeholders" (p. 855). Within the limits of

available resources and their efficient use, who and what should be given attention? To that end, these researchers distinguished claimants versus influencers, actual versus potential relationships, and an array of factors of power, dependence, and reciprocity relevant to the conditions and qualities of relationship networks.

Mitchell *et al.*'s quest was to determine the added value stakeholder identification and participation could yield. The best theory and set of best practices yield the most benefit—add the most value to the relationship—at the most expedient cost. Upon this logic, Mitchell *et al.* [6] offered a taxonomy for stakeholder identification. It features *interdependence* of power (within each relationship and over resources), the *legitimacy* of the power, and the claims it is used to make. In addition, their discussion features the *urgency* of stakeholder claims and the *salience* of any of many claims among competing stakeholders. Viewed in this way, stakeholder theory features an array of variously interdependent stakeholders, which in idiosyncratic ways support or oppose various measures and choices relevant to an organization's management and operations.

Even a superficial review of the literature on this topic can suggest that stakeholders in practice are typically viewed as members of the "general public." Closer review reveals a variety of generic categories: activist publics, intraindustry players, interindustry players, potential activist publics, customers, employees, legislators, regulators, judiciary, investors, neighbors, standard media, and social media [7]. Discussions of stakeholder participation can limit attention to concern over activists, customers, and concerned citizens—and even citizens who are "not concerned but should be." In fact, stakeholder theory and participation reasons that intraindustry or interindustry players (or governmental agencies, as well as other activist groups to activists) may be as important or more important, as might be investors; and they might be customers, or potential customers; voters or potential voters.

The sophisticated trend is to engage in thoughtful consideration of who counts, why

they count, and the nature and quality of the relationship and motives to grant or hold resources are keys to understanding stakeholder participation. The central question regarding who counts is to look for interests and who can add value to discussions leading to better alignment of those interests.

At one level of analysis, the key theme of stakeholder participation centers on how various structures and functions can engage productively with the organization's stakeholders so that the organization can succeed, especially in a competitive marketplace where other organizations (with business, nonprofit, or governmental) compete for tangible and intangible resources. As well, power and the dynamics of participation depend on how power resources are defined and interpreted by various stakeholders in ways that give advantage to some players and disadvantage to others.

To determine who and what really counts—and why, Mitchell *et al.* [6] proposed a *normative theory of stakeholder identification*, which can be used “to explain logically why managers should consider certain classes of entities as stakeholders” (p. 853). The other key option, the *descriptive theory of stakeholder salience*, can offer insights “to explain the conditions under which managers do consider certain classes of entities as stakeholders” (p. 853).

Stakeholder analysis coupled to an interest in effective management brings about traditional concerns for effective management philosophies and relationship management as both a problematic for organizational effectiveness as well as the systemic and ethical or normative qualities of society. In essence, effective stakeholder participation not only helps organizations to be more successful but it also can enrich societies by bringing various interests to bear constructively on one another. This conclusion is based on the logic that what advances the interests of one entity at the disadvantage of others may hurt all; and, if each entity works for the mutual good of all of the various societal interests in society, it therefore operates more successfully as a means for collective risk management.

In defining the nature of the relationship, focus can be given to basic resource dependency, independency, or interdependency. For instance, a seller cannot exist without a buyer (as stakeholder). So too, a buyer (as stakeholder) needs a seller (stakeholder). Likewise, the interdependency extends to matters of issues management, the essential tug of war over policies that define the public and private sectors and their interconnectedness. Each entity needs resources held by the other. This paradigm is central to resource dependency theory which focuses attention on the question: What must organization A do to get stakeholder group A to grant stakes held (as resources)?

Stakeholder participation can be dysfunctional as in the case when an organization can achieve a closed-loop exchange by which interdependence becomes dependence; such conditions ultimately foster attempts by the dependent party to achieve independence. Interdependence becomes distorted when buyers are dependent on the seller for income. That model operated in the United States when company stores dominated mining or timbering towns and during the practice of sharecropping. Miners or loggers earned script which could only be used at the company store. As sharecroppers, farmers borrowed against their crops and sold their crops to the owner who was able to keep the farmers in perpetual debt. Thus, in answer to the question that de Bussy [4] raised, this system operated because one participant could control the stakes and the conditions of their exchange. But, is it sustainable?

Stakeholder participation requires knowing who they are and what they seek and hold, the positions they take on key issues. Does that align with or conflict with the organization's interests, positions, and policies? Who or what must change to reduce conflict and advance alignment? How can discourse advance and hinder the willingness and ability to exchange stakes?

ENGAGING STAKEHOLDERS: NEGOTIATING OR PLAYING HARDBALL

Conflict theory and stakeholder theory interconnect by the assumption that as one entity

works to achieve some goal, other entities can exert power resources that help or hinder (control or constrain) that effort. Cooperation and collaboration are characterized by one entity reciprocally granting power resources the other needs (whether voluntarily or under pressure) to achieve its goals. Competition and conflict result from efforts to use resources to constrain, and even defeat the other organization, or person. In this equation, the resources held, the skilled use of the resource, and the ethics that motivate granting or withholding become important factors of engagement.

Game theory presumes a zero-sum outcome where one entity does better at the expense of another. The contrary option is non-zero-sum game. Thus, there could be lose-lose outcomes where the conflict (or game) as played out leads both sides to a net loss. Another option is win-loss. And the optimal strategy is win-win, typically featured as the process of collaboration, joint problem solving where each side seeks to advance its interests but does so by working to advance (rather than deny) the interests of the other entity or entities engaged in power resource endeavors.

Stakeholder participation rests on pragmatism and ethical principle. Stressing the pragmatics of participation, Freeman [2] offered two options: Negotiation or playing hardball. At the heart of stakeholder participation is the identification of stakeholders, the stakes that each stakeholder holds and those sought by each stakeholder, and the conditions (however voluntary) that influence the willingness and ability of each to engage in stake exchanges, however, mutually beneficial. Freeman [2] stressed the importance of featuring the organization as the focal hub surrounded by stakeholders as each of many spokes.

Rowley [11] reasoned that theorists and practitioners should move beyond addressing stakeholder participation as dyadic ties or one-to-one interconnectiveness to determine which stakeholders count and what drives participation with them. "Since stakeholder relationships do not occur in a vacuum of dyadic ties, but rather in a network of influences, a firm's stakeholders are

likely to have direct relationships with one another" [11]. Stakeholder influence is best approached through social network analysis which "accommodates multiple, interdependent stakeholder demands and predicts how organizations respond to the simultaneous influence of multiple stakeholders" (p. 887). To this end, "the density of the stakeholder network surrounding an organization and the organization's centrality in the network influence its degree of resistance to stakeholder demand" (p. 888). By this logic, four archetypal responses are likely depending on pressures related to density: Commander, compromiser, subordinate, and solitary. As an aside, it's worth noting how in the past decade people have become obsessed with terrorism; the role of solitary has become much more salient than it previously was in stakeholder discussions.

This line of reasoning stresses the dynamics operating between a focal organization and its stakeholders as well as those between various or all other stakeholders. At least two factors are made relevant by this kind of analysis. First, stakeholder participation is driven by *collective expectations* of what each stakeholder wants or desires from others, and how each interprets the expectations on it by others in the exchange network. Second, *density* becomes a factor, at least because "dense networks furnish stakeholders with the capacity to monitor the focal organization's actions more efficiently" [11]. *Density* predicts the ease of information exchange between stakeholders and how readily they create and use coalitions. In addition to density, *centrality* features each stakeholder's position in networks and its ability and willingness to relate to and influence, as well as be influenced by others. Centrality predicts an organization's ability to resist or engage stakeholder pressure. By this logic, Rowley advanced the archetype-driven logics that compromisers are in high density/high centrality conditions, whereas commanders are in high centrality but low density. Subordinates are in high density networks but are low in centrality. The solitary is characterized by low density and low centrality.

Negotiation, and even hardball, become stakeholder participation options when relationships are dense and players are central to networks as well as when collective expectations guide willingness and ability to exchange stakes systematically.

Preferring to avoid characterizing conflict as functional/dysfunctional, Behfar and Thompson [12] preferred a quasifunctional framework “that recognizes boundary conditions and the temporal or contextual aspects of group functioning” (p. 3). Their analysis cautioned against stereotyped assumptions about how functions succeed or fail merely because of presumed motives and conditions of engagement. Thus, they recognize that some who are attentive to improving processes of stakeholder engagement see within-industry conflict as grounds for effective problem solving whereas the conflict with issue activist groups (such as those opposing gender bias or environmental policy) is characterized as flawed and dysfunctional. “Whereas the potential of between-group negotiation is highlighted theoretically, groups often fail behaviorally to fully realize their potential. The ‘quasi’ nature of conflict again demands careful procedures and management to determine how the conflict will manifest between groups” (p. 26). Battles between industry and regulatory stakeholders may thrive when high technical expertise prevails over social skills. Those factors conversely are likely to lead to dysfunctional conflict during issue conflicts with nonindustry groups. With those groups, technical risk assessment and management battles without strong social skills may produce dysfunction between companies, governmental agencies, activist publics, and lay publics.

This line of argument becomes even clearer and more operational under the claim that “relationships shape negotiations, and negotiations shape relationships through socially driven and situated definition, enactment, and interpretation of conflict and exchange” [13]. Playing out this theme, McGinn addressed the importance of attributions and emotions, knowledge structures (shared technical and experiential knowledge), procedural rules and norms,

and coordinated actions, and information sharing. These conditions predict in various ways and in context the distribution and integration of resources (stakes) that result in productive or unproductive negotiations and other modes of conflict resolution.

However much biases, emotions, shared (or lack of) knowledge, shared (or conflicting) interpretation schema, objectives, points of reference, and expected utilities drives conflict resolution in general, it is an inherent problematic of stakeholder participation. To these, one can add factors of centrality, density, shared and collective expectations, claimants versus influencers, actual versus potential relationships, and an array of factors of power, dependence, and reciprocity relevant to the conditions and qualities of relationships.

ENGAGING STAKEHOLDERS: PARTICIPATION THROUGH COLLABORATION

Scholarship features descriptive and normative approaches to stakeholder identification and participation. Negotiation arises as key players known to one another exercise their stakes within interdependent relationships. As a normative challenge, the organization may decide to know descriptively who the players are/should be ethically within dependent or independent relationships. Reflecting this normative theme, Gregory *et al.* [14] observed, “Multiparty deliberative processes have become a popular way to increase public participation in public policy choices” (p. 4). Instead of resulting through interdependence, processes may need to be created by organizations seeking to build relationships and resolve issues through collaborative decision making. This logic drove the creation of, for instance, citizen’s advisory councils. Such engagement is both a pragmatic/functional strategy and an ethical choice on the part of organizations engaging in stakeholder participation. The legitimacy of such processes “depends on participant’s ability, first, to understand the issues facing them and, then, to form and express their own positions on them.

These tasks pose significant cognitive and emotional challenges” (p. 4).

Clarkson [15] recommended differentiating stakeholder issues, which are relationship specific, to societal issues which are more generally matters addressed even well beyond the specific points of stakeholder/stakeseeker interaction. Rather than viewing corporate social responsibility as something based on absolute principles, for instance, he proposed “that corporate social performance can be analyzed and evaluated more effectively by using a framework based on the management of a corporation’s relationships with its stakeholders than by using models and methodologies based on concepts concerning corporate social responsibilities and responsiveness” (p. 92).

Stakeholders operate in relationships predicated on the likelihood that stakes are more likely to be willfully exchanged with organizations that meet or exceed their expectations as opposed to organizations that fall short of expectation. These expectations can take the form of preferred positions on issues that might variously be stakeholders’ issues or social issues. These are not independent, but take on idiosyncratic qualities as they are applied to define stakeholder relationships and justify the meeting of expectations. Corporate (social) responsibility, in its many forms, becomes a meeting place for the discussion and enactment of standards of performance that meet expectations and help rather than harm relationships needed for productive stake exchange.

Whereas other aspects of stakeholder engagement presume that stakeholders knowingly hold stakes and are willing and able to employ them as power resources, Arnstein [16] worried four decades ago that community engagement often failed because participation was attempted without a redistribution of power. The era of her concern was that in which ordinary citizens were learning the power resource ropes of community activism. But the caution she raised is important for stakeholder participation best practices today. Can engagement occur because the right people are asked to become engaged and are they or can they

be convinced that engagement counts? Her ladder of citizen participation postulated citizen power through citizen control, delegated power, and partnership. Tokenism results in the presence of placation, consultation, and information (especially, one might add, when risk communication entails data dumps or discourse involving highly technical knowledge). Lastly, she postulated that nonparticipation resulted when engagement was seen as therapy or therapy was substituted for engagement and when publics were manipulated or coopted. In the lower rungs on the ladder, support might be engineered rather than being the genuine result of ethical and functional systems.

Considering definable targets of engagement, McComas *et al.* [17] noted that complex decisions based on highly technical information can pit those who understand such topics against those who worry about their risk level and who challenge their more knowledgeable adversaries’ right to make decisions that defy public understanding. How can concerned citizens mature into policy makers (recall the ladder of citizen participation)? Strategies may differ when engaging in stakeholder participation with those who believe they have the knowledge and ethical judgment to work for negotiation, and even play hardball.

McComas *et al.* suggested a four-step decision process should begin by finding concerned citizens or those who can become concerned citizens before their opinions are tightly held. With both general types of citizens, engagement might also introduce other discussants who not only understand and facilitate the discourse but also appreciate the value and interpretative disparities that might be at play. Efforts and commitments can be made to foster understanding and seek information that is needed to address concerns and might not be readily available to the collaboration. The second step requires highlighting “the importance of thinking carefully about the problem at the forefront of the consultation” (p. 371). “Helping participants to distinguish between *means* and *ends* objectives also allows for greater creativity in identifying alternatives for evaluation in decision making” (p. 372). This moment in stakeholder participation can be troubling

for those organizations whose intention with stakeholder participation is to engineer consent for their preferred solution (recall the ladder of citizen participation). Finally, one key ingredient in effective stakeholder participation is to select alternatives and address trade-offs as a means for discovering alignment of interests that lead to productive stake exchanges. "This analysis is conducted by carefully analyzing the predicted consequences of each alternative against the participants' stated objectives" (p. 373). In such collaboration, procedural justice matters not only as a means for evaluating the quality of participation but as motivation for its continuation. In such matters, there can be rational, socioeconomic, and relational incentives.

Confronted with its mission/vision and traditional sets of operations, organizations can encounter their own mind set as a hindrance to collaborative stakeholder engagement. If stakes are expressions of values and interests, a multiple-objective decision analysis is required to achieve effective stakeholder participation [18].

CONCLUSION

Discussion of stakeholder participation can be approached in descriptive, normative, instrumental, and managerial fashions [19]. From whatever perspective, stakeholder participation raises a universal concern: the challenge to determine what factors shape the quality of relationships between and among various organizations, corporations, and governmental agencies and the conditions of exchange. As Donaldson and Preston [19] advised, "Stakeholder management requires, as its key attribute, simultaneous attention to the legitimate interests of all appropriate stakeholders, both in the establishment of organizational structures and general policies and in case-by-case decision making" (p. 67).

Featuring a dynamic conception of management and operations, Mumby [20] reasoned, "Organizations are not stable, fully integrated structures. Rather, they are the product of various groups with competing

goals and interests. An organization services a group's interests to the extent that it is able to produce, maintain, and reproduce those organizational practices that sustain that group's needs" (p.166). The logic of that statement can be clarified and expanded by noting that the satisfaction of a group's needs interlock and align with the satisfactions of multiple, networked, and rationalized groups' needs, wants, and interests. By this logic, markets and public policies result from the structures of stake exchange and the meaning that makes them enactable interests.

REDUNDANCY

“Redundancy (in reliability, maintainability, and availability) is the existence of a means in addition to the means which would be sufficient for a functional unit to perform a required function or, for data, to represent information” [1]. Redundancy is used primarily to improve reliability, availability, and/or performance. Reliability and performance requirements are often in contrast: redundancy goals focus on implementing *fault tolerance*, that is *“the ability of a system or unit to continue normal operation despite the presence of hardware or software faults”* [2], while performance requirements mainly involve reduction of the system response time and optimization–maximization of the resources/components throughput and utilization. Thus, in the former case, in order to optimize the system reliability, redundant resources/components, units or subsystems are managed by applying specific redundancy policies, by which few units are operating ones and the others act as spares (*active/standby redundancy*). While, in case of performance redundancy, all the redundant components are operating, working in parallel and thus, sharing the workload (*load sharing*).

There are essentially two kinds of redundancy techniques employed in fault-tolerant designs, *space redundancy* and *time redundancy*. Space redundancy provides separate physical copies of a resource, function, or data item. Time redundancy, used primarily in digital systems, involves the process of storing information to handle transients, or encoding information that is shifted in time

to check for unwanted changes. Space, or hardware redundancy (hereafter only redundancy), is the approach most commonly associated with fault-tolerant design.

Redundancy does not just imply a duplication of hardware because it can also often be implemented by coding, at the software level. However, to avoid common mode failures, redundant elements should be realized (designed and produced) independently from each other. Irrespective of the failure mode (e.g. shorts or opens), redundancy still appears in parallel on the reliability block diagram.

From the operating point of view, one distinguishes between active and standby redundancy [3,4]:

- *Active Redundancy*. Redundant elements are subjected from the beginning to the same load as operating elements and load sharing is possible. External components are not required to perform the function of detection, decision, and switching when an element or path in the structure fails. The redundant units are always operating and automatically pick up the load for a failed unit.
- *Standby Redundancy*. Redundant elements can be energized or not until one of the operating elements fail, no load sharing is possible; failure rate in the reserve state can be lower than in the operating state or also assumed to be zero. External elements are required to detect, make a decision, and switch to another element or path as a replacement for a failed element or path.

Figure 1 introduces an overview of the most important techniques developed in order to achieve redundancy. The distinction between Active and Standby redundancy is there clearly depicted, even if the *k-out-of-n* redundancy technique can be classified as hybrid, implementing aspects of both active and standby redundancy.

Figure 1. Redundancy technique taxonomy.

According to this classification, *standby redundant systems* are those systems composed of two or more units/components/sub-systems with similar functionalities and that each of them can substitute one of the other redundant units in the system functioning, acting as a spare. The main characteristic of standby redundant systems is the *standby policy* applied to manage the redundant units, usually with the aim to maximize/optimize the system reliability/availability, and/or to reduce the down time.

In order to better investigate standby redundancy, an interesting characterization of standby redundant systems reliability and availability that can be useful in the following is made in Ref. 5, distinguishing among three classes:

- **Basic Reliability/Availability.** A system which is designed, implemented, and deployed with sufficient components (hardware, software, and procedures) to satisfy the system's functional requirements, has basic reliability/availability. Such a system will deliver the correct functionality so long as no faults occur and no maintenance operations are performed. Whenever a fault occurs or a maintenance operation is performed, however, an outage may be observed. Typically, basic reliability/availability systems are deployed as simplex (nonreplicated) systems.

- **High Reliability/Availability.** A system which is designed, implemented, and deployed with sufficient components to satisfy the system's functional requirements, but which also has sufficient redundancy in components (hardware, software, and procedures) to mask certain defined faults, has high reliability/availability.

"Sufficient" and "certain" are terms related to the masking concept. "Masking" a fault implies shielding the external observation of the failure, this does not ensure that the fault will not occur, but that it is unobservable. This is invariably achieved through a replication mechanism appropriate to the component, a redundancy strategy. When a component fails, the redundant component replaces it. In this context, sufficient redundancy implies that hardware, software, and procedure faults must all be masked; that is, adequate replication mechanisms or redundancy strategies have to be implemented, also being aware that certain defined faults can be covered, since not all faults can be masked.

The degree of "transparency" in which this replacement occurs can lead to a wide variation of systems which call themselves high reliability/availability, that can be identified as the following:

- **Hot Standby.** Active and redundant components are tightly coupled in

groups and (logically) indistinguishable to the users of the component group. Indeed, the user does not “see” the group, but only the component behavior it requires. Following a component fault, users of the component are not disconnected and do not observe the fault in any way.

- *Warm Standby.* Following a component fault, the redundant system is unreliable/unavailable till a warm standby spare (partially loaded/energized) becomes fully operating. Users of the component are disconnected and may lose *some* of their work in progress. An automatic fault detection and recovery mechanism detects the fault, and notifies the redundant component to take over. This redundant component has been actively running, and is partially initialized.
- *Cold Standby.* Following a component fault, the redundant system becomes unreliable/unavailable till a cold standby spare (starting from scratch) becomes operating. Users of the component are disconnected and lose *any* work in progress. An automatic fault detection and recovery mechanism then detects the fault, and brings into service the redundant component.
- *Manual Masking.* Some manual action is required to put the redundant component into service after a fault, during which time the system is unavailable for use. It could be considered as a standby management policy as above with a manual fault detection and recovery mechanism.
- *Continuous Reliability/Availability.* This extends the definition of high reliability/availability and applies it to planned outages as well. High reliability/availability, as defined above, compensates for unplanned outages. Continuously reliable/available systems must also have a masking strategy that deals with planned outages.

High availability identifies and classifies four *standby policies* for managing standby redundant systems. Automatic techniques, implementing hot, warm, and cold standby policies, are of particular interest in the specific literature and thus are studied in depth in the following sections.

From the reliability point of view a component in hot standby could be considered as active, since it is always characterized by the same reliability CDF, also after changing from standby to active and vice versa. This behavior needs further investigation. In order to do that, let us compare a simple active redundant system composed of two independent and identically distributed units connected in parallel, against a similar configuration in which, instead, a hot standby redundancy policy is applied. It is possible to observe that, in general, a significant difference between the two redundant systems exists: in the former case, the load can be shared between the two units, while a hot standby spare replicates the primary unit task or is fully synchronized to this latter in order to be ready to substitute it in case of failure. Thus, in the standby redundant configuration, the load is not shared among the redundant units; the hot standby unit is kept readily available in order to minimize, ideally to annul, the downtime. If the primary unit implements a stateful process, to achieve the goal of hot standby becomes more complex since it is necessary to constantly refresh the state of the hot standby unit. With this aim, mainly referring to software contexts, specific techniques, grouped together as *active replication*, have been implemented.

The term *active replication* is used to describe a set of techniques used to achieve hot standby, by actively and completely sharing processing state between replicas. In such cases, sharing state implies not only transferring information between replicas, but also coordinating and synchronizing the information. In fact, “state” is a dynamic entity in a distributed system, and changes frequently. Replicas present their state externally, and process it internally, in a consistent manner. “Synchronizing” a system’s state really means ensuring that operations are applied in the same order to all participant replicas.

Active replication techniques are thus largely concerned with ordering operations (an example is the virtual synchrony model [6]). The various active replication techniques available (causal ordering, total ordering, etc.) are attempts to trade-off more or less rigorous ordering guarantees with their respective performance overheads (in general, the more rigorous the order, the more degraded is the performance). In addition to providing an ordered communications vehicle, active replication systems need mechanisms to support the notions of “groups” of replicas, and have membership services which identify, in a distributed sense, which processes are members of a group at any time. Mechanisms are needed to allow members to join a group and “catch up” with the processing state of the group, and to be removed from a group either voluntarily or in response to a detected failure in a member. Hence, active replication systems invariably include failure detection and heartbeat mechanisms as part of their group membership services. Active replication is frequently associated with the notion of “make forward progress” systems, since by maintaining consistent server replicas, clients are not interrupted in the event of a failure, and are always able to advance the state of their work.

Passive or lazy replication describes a set of techniques used to achieve warm standby. Recall that warm standby was defined as a replicated system in which some amount of initialization and state sharing occurs between replicas. In practice, warm standby solutions are often used as a relaxed form of “hot standby” high availability, because active replication can be quite costly in terms of performance and system design complexity. The amount of “relaxation” from the stringent active replication varies, however, so that there are many approaches which can legitimately call themselves warm standby, but which have widely differing amounts of initialization and state sharing. Lazy replication is frequently associated with the notion of “Rollback & Recover” systems, since even with some state maintenance, clients are interrupted in the event of a failure, and must explicitly rebound to the standby.

STANDBY REDUNDANT SYSTEMS

A system is said to have units which are reliability-wise in standby when there is an active unit or subsystem to which are attached units or subsystems which stand by idly during the mission either in a quiescent/nonoperating or warm-up mode, until they are called upon to operate. A sensing subsystem has to detect a failure in the active unit or subsystem and to command the switching subsystem to switch in the standby unit or subsystem. This is unlike the reliability-wise parallel system in which all units start to operate simultaneously at the beginning of the mission, and the system succeeds when at least one unit completes the mission successfully.

Summarizing, a standby redundant system can be composed of three main parts as shown in Fig. 2:

- *Redundant Subsystems, Connected in Parallel.* In this, one or more of them are operating (e.g., by applying specific k -out-of- m voting mechanism), the others are in standby, acting as spare units that substitute the operating ones on faults in order to ensure the redundant system reliability/availability.
- *Switching Subsystems.* A switch for each spare is necessary in order to transition the spare from the standby to the operating state. Such subsystems contain both, the switch device (switches, valves, etc.) and the switching actuator.
- *Monitoring–Sensing Subsystem.* A sensor monitoring the standby redundant system is necessary. It drives the corresponding switch, triggering the switching actuators.

In order to provide a quantitative evaluation of a standby redundant system, we investigate the reliability of a two-unit standby configuration as the one shown in Fig. 2. Let us assume a warm standby policy is applied to S2, so that it is in a warm standby till unit S1 is operating. Following the reasoning applied in Ref. 7, such a system succeeds in its mission with mission time T , when

Figure 2. Two-unit standby redundant system.

1. the active unit does not fail ($R_1(T)$) and the sensing subsystem does not fail ($R_{SE}(T)$) and the switch does not fail open during the mission ($R_{SWO}(T)$), in total $R_{Ev1}(T) = R_1(T) R_{SE}(T) R_{SWO}(T)$, or
2. the active unit fails before the end of the mission at $0 < T_1 \leq T$ ($\int_0^T f_1(T_1) dT_1$; $f_1(T) = -dR_1(T)/dT$) and the sensing ($R_{SE}(T_1)$) and switching subsystems do not fail in both open ($R_{SWO}(T)$) and close ($R_{SWC}(T)$); moreover, the switch ($R_{SWC}(T_1)R_{SWO}(T)$) and the actuator ($R_{ACT}(T_1)$), and the standby unit, not having already failed, succeeds for the remainder of the mission.

Thus, from Ref. 7, we obtain that $R_{Ev2}(T) = \int_0^T f_1(T_1) R_{SE}(T_1) R_{SWO}(T) R_{SWC}(T_1) R_{ACT}(T_1) R_{20}(R_{20}^{-1}(R_{2S}(T_1)) + T - T_1) dT_1$ and therefore, the overall reliability of the two-unit standby redundant system is

$$\begin{aligned}
 R_{2SRS}(T) &= R_{Ev1}(T) + R_{Ev2}(T) \\
 &= R_1(T) R_{SE}(T) R_{SWO}(T) \\
 &\quad + R_{SWO}(T) \int_0^T f_1(T_1) R_{SE}(T_1) \\
 &\quad \times R_{SWC}(T_1) R_{ACT}(T_1) R_{20} \\
 &\quad \times (R_{20}^{-1}(R_{2S}(T_1)) + T - T_1) dT_1.
 \end{aligned} \tag{1}$$

In the hot standby case, $R_{20}(T) = R_{2S}(T) = R_2(T)$ Equation (1) becomes

$$\begin{aligned}
 R_{2SRS}^H(T) &= R_1(T) R_{SE}(T) R_{SWO}(T) \\
 &\quad + R_2(T) R_{SWO}(T) \int_0^T f_1(T_1) R_{SE}(T_1) \\
 &\quad \times R_{SWC}(T_1) R_{ACT}(T_1) dT_1.
 \end{aligned} \tag{2}$$

In the cold standby case, $R_{2S}(T) = 1$ and $R_{20}(T) = R_2(T)$ and therefore,

$$\begin{aligned}
 R_{2SRS}^C(T) &= R_1(T) R_{SE}(T) R_{SWO}(T) + R_{SWO}(T) \\
 &\quad \times \int_0^T f_1(T_1) R_{SE}(T_1) R_{SWC}(T_1) \\
 &\quad \times R_{ACT}(T_1) R_2(T - T_1) dT_1.
 \end{aligned} \tag{3}$$

Equation (1) can be simplified by making the assumption that the switching and the sensing subsystems cannot fail. In this case, Equations (1), (2), and (3) become respectively:

$$\begin{aligned}
 R_{2SRS}(T) &= R_1(T) + \int_0^T f_1(T_1) R_{20} \\
 &\quad \times (R_{20}^{-1}(R_{2S}(T_1)) + T - T_1) dT_1,
 \end{aligned} \tag{4}$$

$$\begin{aligned}
 R_{2SRS}^H(T) &= R_1(T) + R_2(T) \int_0^T f_1(T_1) dT_1 \\
 &= R_1(T) + R_2(T)(1 - R_1(T)),
 \end{aligned} \tag{5}$$

$$\begin{aligned}
 R_{2SRS}^C(T) &= R_1(T) + \int_0^T f_1(T_1) R_2(T - T_1) dT_1 \\
 &= R_1(T) + f_1(T) * R_2(T),
 \end{aligned} \tag{6}$$

where $*$ is the symbol of convolution. Equations (5) and (6) can be generalized to a standby redundant system composed of $n - 1$ spare components (n in total):

$$\begin{aligned}
 R_{n\text{SRS}}^H(T) &= R_1(T) + R_2(T)(1 - R_1(T)) + \dots \\
 &\quad + R_n(T) \prod_{i=1}^{n-1} (1 - R_i(T)), \quad (7) \\
 R_{n\text{SRS}}^C(T) &= R_1(T) + f_1(T) * R_2(T) + \dots \\
 &\quad + (((f_1(T) * R_2(T))' * R_3(T))' * \dots)' \\
 &\quad * R_n(T) = R_1(T) + f_1(T) * R_2(T) \\
 &\quad + \dots + f_1(T) * R_2(T) * (-f_3(T)) \\
 &\quad * \dots * (-f_n(T)). \quad (8)
 \end{aligned}$$

The terms of Equation (8) are obtained as a generalization of Equation (6) by recursively applying this latter at each failure. Moreover, the final formula is obtained by exploiting the derivative convolution rule establishing that $d(f * g)/dx = df/dx * g = f * dg/dx$.

The exponential distribution is often used in reliability theory because of its mathematical tractability. In case all the components, switches, and actuators of the system are characterized by exponentially distributed reliability, Equation (1) becomes

$$\begin{aligned}
 R_{2\text{SRS}}(T) &= e^{-(\lambda_1 + \lambda_{\text{SE}} + \lambda_{\text{SWO}})T} + e^{-\lambda_{\text{SWO}}T} \\
 &\quad \times \int_0^T \lambda_1 e^{-(\lambda_1 + \lambda_{\text{SE}} + \lambda_{\text{SWC}} + \lambda_{\text{ACT}})T_1} \\
 &\quad \times e^{-\lambda_{2\text{O}}((\lambda_{2\text{S}} - \lambda_{2\text{O}})/\lambda_{2\text{O}})(T_1 + T)} dT_1 \\
 &= e^{-(\lambda_1 + \lambda_{\text{SE}} + \lambda_{\text{SWO}})T} \\
 &\quad + \frac{\lambda_1 (e^{-(\lambda_{\text{SWO}} + \lambda_{2\text{O}})T} - e^{-(\lambda_1 + \lambda_{\text{SE}} + \lambda_{\text{SWO}} + \lambda_{\text{SWC}} + \lambda_{\text{ACT}} + \lambda_{2\text{S}})T})}{\lambda_1 + \lambda_{\text{SE}} + \lambda_{\text{SWC}} + \lambda_{\text{ACT}} + \lambda_{2\text{S}} - \lambda_{2\text{O}}}. \quad (9)
 \end{aligned}$$

In case of perfect switching and sensing systems, $\lambda_{\text{SE}}, \lambda_{\text{SWC}}, \lambda_{\text{SWO}}, \lambda_{\text{ACT}} = 0$, and thus $R_{2\text{SRS}}(T) = e^{-\lambda_1 T} + \lambda_1 (e^{-\lambda_{2\text{O}} T} - e^{-(\lambda_1 + \lambda_{2\text{S}})T}) / (\lambda_1 + \lambda_{2\text{S}} - \lambda_{2\text{O}})$, that in case of cold standby ($\lambda_{2\text{S}} = 0, \lambda_{2\text{O}} = \lambda_2$) is $R_{2\text{SRS}}^C(T) = e^{-\lambda_1 T} + \lambda_1 (e^{-\lambda_2 T} - e^{-\lambda_1 T}) / (\lambda_1 - \lambda_2)$. If $\lambda_1 = \lambda_2 = \lambda$, such a formula is indeterminate, but

from Equation (6), it has $R_{2\text{SRS}}^C(T) = e^{-\lambda T} + \int_0^T \lambda e^{-\lambda T} dT_1 = e^{-\lambda T} + \lambda e^{-\lambda T} T = e^{-\lambda T} (1 + \lambda T)$. Such a formula can be generalized for a system composed of $n + 1$ redundant elements. A similar standby system can be considered as a system composed of a single unit that can tolerate n consecutive faults before fails. The n th fault will drive to the failure of the system. In this way, the reliability of a system tolerating $n - 1$ faults is [8,9]

$$\begin{aligned}
 R_{n\text{SRS}}^C(T) &= e^{-\lambda T} \left(1 + \lambda T + \frac{(\lambda T)^2}{2!} + \dots + \frac{(\lambda T)^{n-1}}{(n-1)!} \right) \\
 &= e^{-\lambda T} \sum_{i=0}^{n-1} \frac{(\lambda T)^i}{i!}. \quad (10)
 \end{aligned}$$

STANDBY REDUNDANT SYSTEMS MANAGEMENT

Once the main components and parts of a standby redundant system have been identified, along with the way, the management policies that can be applied to spares (cold, warm, hot), specific configurations, techniques and strategies to apply to the standby redundant system in order to improve its reliability and availability are investigated. In particular, issues related to *k-out-of-n* standby redundancy will be studied in depth while aspects such as repairability, standby priority, and optimization will be briefly discussed/outlined due to the extent of such topics.

k-out-of-n Redundancy

A problem that may arise in such systems regards the monitoring and sensing subsystem in the making of a decision: how to establish the correctness of a response? A possible solution is the *voting redundancy* technique [10]. Assume that the same input is applied to two identical digital elements and compare the outputs. If each bit agrees, then either they are both working properly (likely), or they have both failed in an identical manner (unlikely). If a difference between the

two outputs is detected, then there is an error, although it is not possible to establish which element is in error. If a third unit is taken into consideration, in case all three outputs agree, then either all three are working properly (most likely) or all three have failed in the same manner (most unlikely). If two of the element outputs agree, then most likely the element with a different output has failed and the redundant system can rely on the output of the other two elements. Thus with three elements, it is possible to correct one error. If two errors have occurred, it is very possible that they will fail in the same manner, and the comparison will agree (vote along) with the majority. By extending such an idea to N elements, the so-called *N-modular redundancy* technique is obtained. *Majority redundancy* is a special case of a *k-out-of-n* redundancy, used primarily in digital circuits.

Generally, a system consisting of $n \geq 2$ components or subsystems, of which only $1 \leq k \leq n$ need to be functioning for system success, is called a *k-out-of-n* configuration. More specifically, such a configuration is referred as *k-out-of-n:G* (G stands for good) or, alternatively, as *(n-k)-out-of-n:B* (B as bad). In the former case (*k-out-of-n:G*), when $k = n$, the system has a series structure, whereas for $k = 1$, it reduces to a parallel structure, vice versa for *k-out-of-n:B* systems. Thus, a *k-out-of-n* system is more general than either a series or a parallel structure. Hence, the result for this system holds for both series and parallel structures. It is important to remark that all the components of a *k-out-of-n* system are initially operating. Moreover, assuming that all the components of the *k-out-of-n* system have independent and identically distributed lifetime with CDF $F(t)$, pdf $f(t)$ and reliability $R(t) = 1 - F(t)$, the *k-out-of-n* system reliability is

$$R_S(t) = \begin{cases} 1 - F^n(t), & k = 1; \\ \sum_{i=k}^n \binom{n}{i} R^i(t) F^{n-i}(t), & k \geq 1. \end{cases} \quad (11)$$

Equation (11) is obtained by expanding $(R(t) + F(t))^n$. $k = 1$ identifies parallel

systems ($R_s(t) = 1 - F^n(t)$), while $k = n$ corresponds to series ($R_s(t) = R^n(t)$).

As stated above, majority redundancy is a special case of *k-out-of-n* systems, in which $2n + 1$ outputs are fed to a voter whose output represents the majority of its $2n + 1$ input signals. The majority redundancy realizes in a very simple way a fault-tolerant structure without the need for control or switching elements, the required function is performed without interruption until a second failure occurs, the first failure will automatically be masked by the majority redundancy.

The *k-out-of-n* redundancy can be considered as a particular policy that mixes active redundancy for some subsystems and standby redundancy for other subsystems. As in *k-out-of-n* systems, in a *k-out-of-n* redundant configuration (*k-out-of-n:G*), k components are necessary for the system to provide the required function and $n - k$ stay in the reserve-standby state acting as spares, vice versa in *k-out-of-n:B*. Each time a component among the k operating ones fails, a spare is activated, that is switched from standby to operating mode, until there are spares available. When no more spare components are available, the *k-out-of-n* standby redundant system fails.

Assuming, as above, the n lifetime components identically distributed (no more independent due to the standby) having a common CDF $F(t)$, pdf $f(t)$, and reliability $R(t) = 1 - F(t)$, and moreover, ideal failure detection and switching, two different standby are investigated: hot and cold. In the former case, the reliability of a *k-out-of-n* hot standby redundant system corresponds to the one reported in Equation (11), since no changes in the reliability CDF occur for the standby spares at changing points.

More complex is the case of cold standby. A way to solve such a problem is to view it as a particular case of the cold standby system, and thus apply Equation (8). Following such reasoning, it is necessary to identify as primary subsystem of the *k-out-of-n* cold standby redundant system, the series of the k operating components, while the others $n - k$ components are cold spares. In this way, due to the assumption of identically distributed

components, Equation (8) becomes

$$\begin{aligned}
R_{k/n\text{SRS}}^C(T) &= R_1(T) + f_1(T) * R_2(T) + \dots \\
&\quad + f_1(T) * (-R_2(T)) * (-f_3(T)) \\
&\quad * \dots * (-f_n(T)) \\
&= R(T)^k - (1 - R(T)^k) * f(T) + \dots \\
&\quad + (1 - R(T)^k) * (-f(T)) * \dots * \\
&\quad (-f(T)) \\
&= R(T)^k + \sum_{i=k+1}^n (-1)^{i-k} (1 - R(T)^k) \\
&\quad * f(T)^{*i-k}. \tag{12}
\end{aligned}$$

In case of exponentially distributed lifetime components, referring to the equations in Ref. 11 for the i -fold convolution power of exponential pdf $f(T)^{*i} = \lambda(\lambda T)^{i-1}e^{-\lambda T}/(i-1)!$, Equation (12) becomes

$$\begin{aligned}
R_{k/n\text{SRS}}^C(T) &= e^{-k\lambda T} + \sum_{i=k+1}^n (-1)^{i-k} (1 - e^{-k\lambda T}) \\
&\quad * \frac{\lambda(\lambda T)^{i-k-1}e^{-\lambda T}}{(i-k-1)!} = e^{-k\lambda T} + \sum_{i=k+1}^n \\
&\quad \times \left((-1)^{i-k} \left(1 - e^{-\lambda T} \sum_{j=0}^{i-k-1} \frac{(\lambda T)^j}{j!} \right) - (k-1)^{i-k} \right. \\
&\quad \times \left. \left(e^{-k\lambda T} - E^{-\lambda T} \sum_{j=0}^{i-k-1} \frac{((1-k)\lambda T)^j}{j!} \right) \right). \tag{13}
\end{aligned}$$

Repairability

Standby redundant systems can be broadly classified as having nonrepairable or repairable elements [12]. System reliability can be improved by having repairable elements. Maintenance can be either corrective or preventive; corrective maintenance occurs only after the failure of an element. On the other hand, if maintenance and repair are performed before an element fails, then the unit undergoes preventive maintenance. This classification holds for scheduled preventive work as well as for maintenance that is performed as a result of inspection. A good reference on the topic is Ref. 12, that though dating back to 1986, provides an actual,

valid, and interesting classification of the specific topic.

With regard to repairable standby systems, an interesting aspect to consider is *priority management*. The concept of priority in standby redundancy is mainly used to introduce a distinction between the primary/working units and the spare/standby ones: when a primary unit is repaired, the spares activated in substitution of such primary unit, due to the priority of this latter, come back into standby. Otherwise, if priorities are not specified, the primary could become a spare of the operating units, also of the standby ones substituting it.

In Ref. 13, a redundant system consisting of a repairable priority unit and a standby unit is considered. Usually, the priority unit performs the desired system function. On failure of the priority unit, the standby unit is switched into service. Meanwhile, the priority unit is repaired. As soon as repair of the priority unit is completed, it is switched back into service. Priority standby can be contrasted with usual standby with repair, which has been analyzed by Gnedenko [14] and Srinivasan [15]. In usual standby, switchover from one unit to the other does not occur until the operating unit fails, irrespective of which unit is operating. Gnedenko and Srinivasan used simple renewal theory arguments and obtained Laplace–Stieltjes transforms of the time between units. The preemptive priority results are relatively insensitive to the form of successive switchovers. From these transforms, the availability distributions are obtained.

More recently, in Ref. 16, Goel and Kuma Tyagi considered and studied in depth, a priority redundant system with two dissimilar units and three modes: one of the units has a priority operative mode and the other has a priority repair mode. Another interesting work on the topic has been developed by Vanderperre and Makhanov in Ref. 17. In this, the authors consider a two-unit cold standby system attended by two repairmen and subjected to a priority rule. In order to describe the random behavior of the twin system, they employ a stochastic process endowed with state probability functions satisfying coupled Hokstad-type differential equations. Since an

explicit evaluation of the exact solution is in general quite intricate, they proposed a numerical solution of the equations to analyze the long-run availability of the T-system.

Optimization

Another challenge/issue of great importance in standby redundancy and standby redundant system, is the optimization. Several articles address either the provision of redundant components in parallel or the combination of structural redundancy with the enhancement of component reliability. These are called *redundancy allocation problems* and *reliability redundancy allocation problems*, respectively.

The redundancy allocation problem involves the simultaneous selection of components and a system-level design configuration, which can collectively meet all design constraints in order to optimize some objective functions such as system cost and/or reliability [18]. In this problem, there are several different component types with different levels of cost, reliability, weight, and other characteristics, and the components redundant within the subsystem are of the same type. Redundancy allocation problems are well documented in Refs 19 and 20, which employ a special case of reliability redundancy allocation problems without exploring the alternatives of component-combined improvement.

Recently, much of the effort in optimal reliability design has been placed on general reliability redundancy allocation problems, rather than redundancy allocation problems. In practice, only two redundancy schemes are mainly considered: active and cold standby. As discussed above, cold standby redundancy provides higher reliability, but it is hard to implement due to the difficulty of failure detection. Reliability design problems have generally been formulated considering only active redundancy; however, an actual optimal design may include active redundancy or cold standby redundancy or both. However, any effort for improvement usually requires resources. Quite often, it is hard for a single objective to adequately describe a real problem for which an optimal design is required.

For this reason, multiobjective system design problems always deserve a lot of attention.

Optimal reliability design problems are known to be NP-hard [21]. Thus, finding efficient optimization algorithms is always a hot spot in this field. In the past few decades, optimization problems including those of redundancy allocation and reliability apportionment, have been treated by many researchers as nonlinear integer programming (nIP) problems with one or several resource constraints. Furthermore, the practicality in recent process synthesis and process optimization of highly reliable systems leads to an extended system reliability design with the consideration of finding the optimum levels of component reliability and the number of redundant components at each subsystem level. This problem, also identified as optimal reliability assignment/redundant allocation problem, is more difficult than reliability apportionment or redundancy allocation problems, because it should be simultaneously determined by two different types of decision variables.

During the past two decades, numerous reliability design techniques have been proposed. These techniques can be classified as *implicit enumeration*, *dynamic programming*, *branch-and-bound method*, *linear programming*, *Lagrangian multiplier method*, *heuristic methods*, and so on. Tillman *et al.* [22] and Kuo *et al.* [20] have well reviewed the field of optimization techniques for system reliability design in their books. Dhingra [23] researched the reliability apportionment problem for a series system with time-dependent reliability. Hikita *et al.* [24] presented an application of the surrogate-constraints algorithm for an optimal reliability assignment/redundant allocation problem. Jacobson and Arora [25] employed a method combining the simplex searching method and the heuristic approach for a similar problem with the consideration of different starting values. Shelokar *et al.* [26] recently developed an ant colony algorithm to solve both continuous function and combinatorial optimization problems in reliability engineering.

Most of these techniques transform the original problems formulated as an NIP problem into a 0–1 linear programming problem. However, this transformation leads the original problems to an increase in the number of variables and constraints to be treated. This requires much more computation time and larger computation memory space so that researchers in the reliability optimization field have placed more emphasis on the heuristic methods, which yield reasonably good solutions with little computation, even though heuristic methods have some weaknesses in several specific optimization problems. Genetic algorithm (GA) is one of metaheuristic optimization techniques, which include simulated annealing, tabu search, and evolutionary strategies.

GA has been demonstrated to converge to the optimal solution for many diverse and difficult problems as a powerful and stochastic tool, based on principles of natural evolution. For specific engineering problems, however, GA sometimes can suffer from the premature convergence situation of its solution because of its fundamental requirements, that is, not using *a priori* knowledge and not exploiting local search information. Also, it is necessary to adequately tune the unknown GA parameters such as population size, maximum generation, crossover probability, and mutation probability, because they strongly affect a balance between exploitation and exploration in the search space.

Metaheuristic methods, especially GAs, have been widely and successfully applied in optimal system design because of their robustness and efficiency, even though they are time consuming, especially for large problems. To improve computation efficiency, hybrid optimization algorithms have been increasingly used to achieve an effective combination of GAs with heuristic algorithms, simulation annealing methods, NN techniques, and other local search methods.

In this context, Coit and Smith [27] presented a new formulation and solution method for the redundancy allocation problem with mixing components redundant in subsystems. They used a GA to solve this problem in k -out-of- n :G system. Chen and You [28] also presented the use of an immune

algorithm to solve such a problem in a series system. In general, this reliability design problem has been formulated by considering active redundancy. However, the choice of redundancy strategies for each subsystem is much more realistic and it provides a better tool for the designers. This becomes an additional decision variable in a redundancy allocation problem with mixing components redundant in subsystems.

Coit and Liu [29] presented a new formulation and solution method for the redundancy allocation problem when a system design includes multiple subsystems designed with either active or cold standby redundancy. This solution method assumes that the redundancy strategy (i.e., active or cold standby) for each subsystem is predetermined. Coit [30] presented a new formulation and solution method to the RAP when there are some subsystems using active redundancy and cold standby redundancy, or selecting the best redundancy strategy. Furthermore, Tavakkoli-Moghaddam *et al.* [31] used the genetic algorithm to solve the abovementioned problem. Unfortunately, the redundancy allocation problem with mixing components in subsystems is not considered when the redundancy strategy can be chosen for individual subsystems. Thus, the problem is to select the best redundancy strategy, combination of components, and redundancy level for each subsystem in order to maximize the system reliability under system-level constraints.

Most of the above cited works are based on the assumption that the element lifetimes are random variables. Although this assumption has been adopted and accorded with the facts in widespread cases, it is not reasonable in a vast range of situations such as a space shuttle system, where the estimations of probability distribution functions or density functions of element lifetimes are impossible due to the imprecise nature of the data. In this case, fuzzy theory [32–34], which is proposed as a branch of nonadditive measure theory for dealing with subjective uncertain phenomena, is widely employed in term of characterizing the element lifetime as fuzzy variables, and fuzzy redundancy optimization models are then widely studied [35–37].

Beyond fuzzy theory, uncertainty theory initialized by Liu [33] is another branch of nonadditive measure theory for describing subjective uncertain phenomena; this has also been well developed [38,39]. An in-depth investigation of the standby redundancy optimization problem within the framework of uncertainty theory can be found in Ref. 40.

STANDBY SYSTEMS

SALVATORE DISTEFANO
Department of Mathematics,
University of Messina,
Messina, Italy

WHAT IS STANDBY?

According to several dictionaries [1–3] the adjective standby mainly means “ready for emergency use,” or “kept readily available for use as substitute/spare in an emergency, shortage, or the like, of or pertaining to a waiting period.” The adjective derives from the verb stand by [3]: “1. To be ready or available to act. 2. To wait for something, such as a broadcast, to resume. 3. To remain uninvolved; refrain from acting: stood by and let him get away. 4. To remain loyal to; aid or support: stands by her friends. 5. To keep or maintain: stood by her decision.”

From an in-depth analysis of such definitions we can identify a least common multiple for standby, that is the concept of putting aside or shelving, waiting for the occurrence of a specific event. The concept of wait is therefore of primary importance in standby systems: a standby system waits, ready for use, till it will be solicited to act or operate.

Another concept that often, but not always, characterizes standby is the one of *substitute/spare*: in such cases the wait is related to the failure, shortage or outage of a primary system, and the standby system is ready to substitute this latter in its main functionalities, the so-called *standby redundancy*.

Why Standby Systems?

Standby systems are those systems characterized by a double mode of acting, working or operating: full and standby. In the full mode, the system provides its service and functionalities to the environment, while in

the standby mode it does not provide any service and/or functionality although it could do that, waiting for an external input, signal, call, alert that is able to switch the system from standby to full mode.

There are several motivations that justify the introduction and the use of standby systems:

- optimizing cost and resources management, by introducing power-saving policies;
- optimizing the reliability/availability of complex systems, applying standby redundancy policies to their components;
- reducing the environmental impact, as also imposed and specified by several official laws and standards [4–8];
- the necessity of managing a population, a group of systems larger than needed to cover the real demand, introducing specific group management policies in order to keep busy, working the systems' group or to have a large amount of standby resources available.

Examples of standby systems can be found in different contexts and fields of application, such as standby commitments, standby cash, standby letters of credit, standby works in economy, the military standby reserve and standby force, the travel standby list, the standby assistance, the standby juror system, standby actors, standby alarms, and so on. But it is in technological and engineering fields that standby systems find the most varied and valuable applications, stimulating systematic and in-depth studies on the topic.

Standby Systems in Technological Contexts

In technological contexts, the concept of standby is mainly associated with and refers to the energy and/or to the power consumption of the system. Standby power, standby power systems, standby batteries, standby generators, and standby fuel are becoming

popular words increasingly used in plans, projects, data sheets, diagrams, schemes, and technical notes. For this reason standby and related terms have been included in many technical glossaries.

A term of particular interest in technological context (borrowed from electronics) is *sleep mode* and its synonymous *standby mode* [9]: a mode in which electronic appliances are turned off but under power and ready to activate on command. The *standby power* is instead the power used while an electrical device is in its lowest power mode (sometimes called the *off-mode* consumption or the *no-load* power use) [6]. This typically occurs when the product is switched off or not performing its primary purpose [7].

The introduction and the specification of the sleep/standby mode has given rise to a wide spread of standby systems, and consequently has driven the systematic and in-depth study of the topic. This trend has consolidated in the last decade due to the increasing sensitivity toward environment, pollution, and energy-related problems.

From this pulse, many government [6–8,10] and nongovernment [4,5,11] initiatives and projects were born. This has also revolutionized the approach in designing energy-efficient devices and systems, moving toward low-power electronics and focusing on standby management policies in order to optimize the power consumption and/or the reliability/availability of the overall system. For example, in computing contexts, such a trend has led to green computing, that is *the study and practice of designing, manufacturing, using, and disposing of computers, servers, and associated subsystems—such as monitors, printers, storage devices, and networking and communications systems—efficiently and effectively with minimal or no impact on the environment* [12]. Standby systems play a strategic role in green computing.

Remaining in the ICT context, a definition of standby worthy of mention has been provided by the ATIS Telecom glossary 2007 [10] (incorporating and superseding the ANSI T1.523-2001—Telecom Glossary 2000 standard—formerly known as Federal Standard 1037C); it characterizes three cases:

1. *In computer and communications systems operations, pertaining to a power-saving condition or status of operation of equipment that is ready for use but not in use.* (An example of a standby condition is a radio station operating condition in which the operator can receive but is not transmitting.)
2. *Pertaining to a dormant operating condition or state of a system or equipment that permits complete resumption of operation in a stable state within a short time.*
3. *Pertaining to spare equipment that is placed in operation only when other, in-use equipment becomes inoperative.* (Standby equipment is usually classified as (i) *hot standby equipment*, which is warmed up, i.e., powered and ready for immediate service, and which may be switched into service automatically upon detection of a failure in the regular equipment, or (ii) *cold standby equipment*, which is turned off or not connected to a primary power source, and which must be placed into service manually.)

Even though this latter definition is specific for computer and communications systems, it can be easily extended to electronic devices and appliances and, more in general, it can also include energized devices/systems with sleep/standby modes and corresponding power management facilities. In this way, a class of *standby powered systems* can be identified, characterized by a *phantom-load* sleep/standby mode as an alternative to the normal full-load functioning. In the sleep mode, a standby powered system can however be energized although not operating on a load. Such a busy powered wait characterizes the standby state, as also specified in case 3 of the above definition. According to that, the sleep-state condition is associated with both, the power supplied to the system while in standby and the time to resume the system from standby. The lower is the standby power (*hot/warm standby*) the longer is the time to resume the system from standby, since a greater number of its functions/components must be restarted/reinitialized. In case no

power is supplied in standby (*cold*), the system is switched off and therefore its restart can be very long, since the system must restart from scratch. Moreover, sometimes such operations cannot be performed automatically as discussed in the definition.

Such characterization can be extended to the sleep mode of standby powered systems without relating it to the restart/resuming feature, specifying the hot/warm standby in case the system standby mode is fully or partially powered, respectively, and cold standby if the system is not powered at all when in sleep mode.

It is important to note that the term *standby powered system* here introduced should not be confused with standby power system that is *an independent reserve source of electric energy that, upon failure or outage of the normal source, provides electric power of acceptable quality so that the user's facilities may continue in satisfactory operation* [11].

STANDBY SYSTEMS IN RELIABILITY

The standby is a hot topic in reliability, availability, and dependability contexts. It is usually associated with the concept of *redundancy*, implementing techniques and policies for optimizing the system reliability/availability through an adequate management of the redundant components' sleep/standby modes, the so-called standby redundancy; that is, *the use of redundant elements that are left inoperative until a failure occurs in a primary element* [13].

But the notion of standby in reliability/availability is a more general and complex concept that needs to be adequately investigated from a general and abstract point of view, without restricting the discussion to redundancy. In order to provide such a general abstract overview of standby systems in reliability, in the following sections the standby mode will be investigated from both internal/isolated and external/system reliability perspectives; that is, the behavior of a standby system will first be evaluated from an intrinsic point of view, without considering the interactions of

the standby system with the external environment, and then by taking into account such interactions into a more general system reliability viewpoint in which the standby system is included as a component.

From the Inside

In order to evaluate the effect of standby modes into standby systems, it is necessary to characterize the standby state in terms of reliability/availability, specifying the operating condition of a standby system and all the possible states it can assume. Once the standby systems' states are identified, a finer classification of standby can be applied, resulting in three classes.

Standby State. First of all, it is necessary to clearly specify what the standby/sleep mode or state is and means from the reliability/availability point of view. In other words, it is necessary to identify the state a standby system can assume. In system reliability/availability, a system, subsystem, or component can assume two states: up if reliable/available and down if unreliable/unavailable. Such kind of systems, subsystems, and/or components are thus classified as *Boolean*. Standby systems cannot be easily included in the class of Boolean systems, since they are a "borderline" state; it is not easy to classify a standby mode as up or down state. A more specific classification is required.

In Ref. 13, the two main states a system can assume are thus specified:

- *Up*. this pertains to a system or component that is operable and in service. Such a system is either operating or idle.
 - *Operating*. This pertains to a system or component that is operable, in service, and in use.
 - *Idle*. This pertains to a system or component that is operable and in service, but not in use.
- *Down*. This pertains to a system or component that is not operable or has been taken out of service.

Table 1. Standby System State Characterization

State	Feature					
	Operable		Service		Use	
	Yes	Not	In	Not In	In	Not In
Up						
Operating	✓		✓		✓	
Idle	✓		✓		✓	
Dormant	✓			✓		✓
Down						
Failed		✓		✓		✓

In this way, the *up time* is the period of time during which a system or component is operable and in service; that is, the sum of idle time and operating time. The idle time is the period of time during which a system or component is operable and in service, but not in use. The operating time is the period of time during which a system or component is operable, in service, and in use. Finally, the *down time* is the period of time during which a system or component is not operable or has been taken out of service.

Starting from such specification [13], three main features by which the states a system can assume are identified are as follows:

- *operable*—if the system is ready for use in its intended environment;
- *in service*—if the system is ready to provide its functions to the environment;
- *in use*—if the system is performing its intended functions.

While operable and in-use features mainly refer to the standby system from its internal point of view, the in-service feature is instead more specific to the external point of view, and thus it will be discussed in greater detail in the next subsection.

In this way, by applying the above characterization and making all the possible combinations among such features, four states are obtained for a standby system: the three states already identified in Ref. 13 plus a new state, summarized in Table 1: *operating*, *idle*, *dormant*, and *failed*. The operating, idle, and failed (down) states thus correspond

to the one defined in Ref. 13. The new dormant state represents a condition in which, the operable standby system is in its sleep mode waiting for an external trigger event occurrence. Such a new state, from the internal, isolated point of view has to be classified as an up state since the standby system is operable, as also in operating and idle states. The classification can change by considering a different, external, point of view, taking into consideration whether the standby system is in service or not, as done in the next subsection.

In this way, the idle and the dormant states can also be interpreted as two cases of a unique statement, and consequently they can be merged into a unique standby state. The merging of idle and dormant states into standby has a physical interpretation: the former condition (idle) represents the case in which the standby system automatically/self jumps from the operating state into the standby one (and vice versa) if no or reduced load is applied. The state change in such cases exclusively depends on the internal status and on the evolution of the standby system and does not affect the external environment. The latter condition (dormant) describes the case in which the standby switching is driven from external events. In this way, the standby system depends on the external environment, that usually is another component, subsystem or system.

Therefore, since often it is not possible to split the standby behaviors of a system into idle and dormant states due to the nature of the underlying physics phenomena, only a unique standby state is usually specified by merging such states, as already introduced and also confirmed by the specific literature [14–16]. Figure 1 pictorially depicts this fact by specifying the standby system state machine with all the possible states above characterized (rounded rectangles) and the corresponding state changes or events (arrows) a standby system can assume or perform. Four events have been identified for a standby system in the state machine of Fig. 1: *failure*, *resume*, *sleep*, and *repair*. The *failure* event represents transits driving to the failed state: generally systems in both operating and standby states can fail so failure

Figure 1. State machine of a standby system.

events from both these states are defined. The *resume* event switches from standby to operating states, representing the transition from standby mode to full-loaded operating conditions. The *sleep* event switches from operating to standby states, performing the reverse transition of resume events. Finally, the *repair* event implements the reverse path of failure events, representing the repair of the standby system that can be performed from the failed state to both standby or operating states, according to the condition applied to the system after the repair.

Types of Standby. In the section titled “Standby Systems in Reliability,” and more specifically in case 3, we refer to a characterization of standby mode made in Ref. 10 distinguishing between hot and cold standbys, there applied to a more general class of standby powered systems. Other interesting definitions are provided in Ref. 17:

- *Cold Standby.* This is a configuration in which a redundant functional unit can be brought into service with some delay should the primary functional unit fail.
- *Hot Standby.* This is a configuration in which a redundant functional unit can be immediately brought into service should the primary functional unit fail.

The above definitions characterize the standby mode/state by considering the power supplied to a standby system and/or the delay in bringing this latter into service: cold if no power is supplied to the system, introducing a delay for restarting in service, and hot if the system is powered and no delay elapses

for coming into service. In order to translate such classification in reliability terms, it can be observed that usually the power supplied to a system is in direct relationship with the unreliability of the system, that is the greater the energy supplied to the system the higher is its unreliability since the system created more work. This fact is confirmed in particular by the cold standby, since a system that is not powered cannot fail on its own; it can fail only in case of external causes (not considered in this subsection).

Thus, starting from this reasoning, a classification of the standby state in terms of reliability is possible by exploiting such relationships between reliability and power. In this way, three types of standby can be characterized [15,16,18,19]:

- *Cold Standby.* This is a condition/state in which the standby system, subsystem or component cannot fail autonomously.
- *Warm Standby.* This is a condition/state in which the standby system, subsystem or component can fail autonomously, but with reduced failure rate and/or delayed reliability distribution referred to the operating state’s ones.
- *Hot Standby.* This is a condition/state in which the standby system, subsystem or component can fail autonomously and with the same failure rate and/or reliability distribution of the operating state’s ones.

In case of cold standby, the system remains (intrinsically) reliable while in standby. In the other cases (warm and hot), the system can also fail from its standby

state. The warm standby is a case not included in the previous definitions, but it is of particular interest in reliability, and, thus, it has been dealt with here. Warm standby implies that the standby system changes the law or the distribution governing its reliability when the sleep mode is triggered, an effect that has to be adequately represented in terms of reliability. Such behavior is sometimes identified in the specific literature as *delayed aging process* [18].

The hot standby can be considered as a special case of warm standby, in which the standby system is energized as the system in operating condition, and therefore in terms of (intrinsic) reliability, there is no difference among the two conditions. However, it is important to remark that the above characterization of standby is made from an internal perspective, by considering the standby system in an isolated context. Dependent, on demand, cascading, common cause failures, and other similar external events can trigger the failure of the standby system, also in case of cold standby. By changing the perspective, the different concepts expressed here, especially the hot standby one, assume different meanings, as investigated in the following section.

From the Outside

By changing the point of view, the meaning of concepts and their interpretations can change; as a consequence it is necessary to review what is specified in the previous section by observing the standby system from the outside. Till now, we have dealt with standby systems in an isolated context, only discussing about a generic relationship with the external environment. Such a relationship can be considered as a dependent-dynamic interaction between the standby system and the external environment. However, in the system reliability/availability perspective, a standby system is considered as a part or component of a more complex system. More specifically, the main goal of system reliability/availability is the construction of a model (life distribution) that represents the time-to-failure of the entire system, based on life distributions and maintenance policies of

the components, subassemblies, and/or assemblies by which the system is composed.

In our specific case, it is necessary to adequately identify and evaluate the interactions among standby systems, subsystems or components (components hereafter) when they are included or compose more complex systems. Thus, the standby is here represented as a dependent interaction among components, subsystems, or systems. Such interaction involves two sides: the drive component triggering the dependency and the standby component that suffers this.

In order to adequately model and evaluate the standby, specific information regarding and quantifying dependent and dynamic relationships among the components are needed. The reliability/availability distributions in such case become bivariate or multivariate and specific models, such as proportional hazard models [20], frailty models [21], copula-based models, and so on, can be used for expressing the correlation among the components involved in dependent behaviors.

According to such considerations, from the system reliability point of view, the characterization made in Table 1 has to be revised and reinterpreted. Two standby states have been identified there, the idle and the dormant states; then, they have been merged into a unique standby state in the state machine of Fig. 1 and evaluated from an intrinsic point of view, as up states.

The dormant state represents the case in which the standby component depends on other components of the systems driving the standby. In such cases, since the standby component in the dormant state is operable but not in service till the trigger event occurs, from an external perspective the standby component has to be considered as down and out of service. In other words, the down state is characterized by both the failed state and the dormant one. But, while in the former case (failed) an external time-consuming action (repair, replacement, etc.) is needed to restore the operational conditions of the component, in the other case (dormant) the standby component is not physically failed: it is in a dormant state, waiting for an input from its driver component switching the standby component in service.

With regard to the characterization of Fig. 1, where the standby state groups idle and dormant states, the classification of dormant state as down state conflicts with the one identifying idle state as up state. In such cases, in order to classify the overall standby state as up or down in terms of reliability/availability, it is necessary to study in depth, case by case, the underlying physical phenomena and evaluate whether the standby is driven by another component of the system (dormant-down) or not (idle-up).

This can be considered as a drawback of the one-standby-state characterization implemented, but usually it is the only way to represent standby components, since they are characterized by reliability/availability distributions that can change from operating to standby conditions, as discussed in the next section. This fact becomes evident with the specification of three types of standby state (hot, warm, and cold) made in the section titled “Summary.” In particular, the warm and cold standbys are characterized by their own reliability/availability distributions that differ from the operating ones. Therefore, operating and standby states cannot be merged and have to be modeled into separate states, regardless of whether the standby state is classified among up or down states since the reliability/availability distributions of operating and standby states are different.

From such a perspective, the hot standby state that has the same distribution as the operating state, is meaningfully represented only if it is associated with down states since it is clearly distinguished from the operating state that is an up state. In case such a distinction cannot be established, that is the hot standby is identified as an up state, the standby characterization becomes meaningless. Moreover, a component in hot or warm standby state can obviously fail in case the standby is characterized both as an up state and as a down state. Instead, no failures are possible from cold standby states in any case.

Assessing Reliability of Standby Systems

A standby system switches from sleep to operating modes and vice versa if a specific

external event occurs. In terms of probability, this means that the unreliability of the system can be represented by a bivariate CDF $F_{X,Y}(x,y)$ depending on two events: the system time-to-failure X and the conditioning event Y . The problem here is how to obtain the conjunct $F_{X,Y}(x,y)$ CDF by knowing the marginal CDFs $F_X(x)$ and $F_Y(y)$. But, in this way, the problem is ill posed because in general it is not possible to obtain the conjunct CDF from the marginal CDFs; it is necessary to deeply know the dependency between X and Y . Thus since a solution for the generic problem does not exist, some specific cases, fixing precise and circumscribed assumptions on the dependency, have been analyzed.

A representation widely spread in such a context is the *proportional hazard models* one [20], also known as *Cox models*, and in common, cause failure context as *β -factor models* and characterization of the more general *frailty models* [21]. Proportional hazard models express the covariance of the system time-to-failure random variable before and after the occurrence of a specific event influencing the system (the standby trigger) in terms of hazard-failure rate. Discursively, in proportional hazard models, the treatment under study has a multiplicative effect on the subject's hazard rate, that is, in the simplest case, the two hazard/failure rates are proportional.

Thus, the proportional hazard model assumes changing a stress variable (or explanatory variable) has the effect of multiplying the hazard rate by a constant. In more formal terms, a proportional hazard model can be expressed by the following equation [20,22]:

$$h_z(t) = g(z) h_0(t), \quad (1)$$

where $z = \{x, y, \dots\}$ is a vector of one or more explanatory variables believed to affect lifetime, $h_0(t)$ is the hazard rate for a nominal (or baseline) set $z_0 = (x_0, y_0, \dots)$ of these variables, and $h_z(t)$ is the function describing the hazard rate for a new value of z .

In other words, changing z , the explanatory variable vector, results in a new hazard function that is proportional to the nominal

hazard function and the proportionality constant is a function of z , $g(z)$, independent of the time variable t . A common and useful form for $f(z)$ is the log linear model which has the equation $g(x) = e^{ax}$ for one variable, $g(x, y) = e^{ax+by}$ for two variables, and so on. For a more detailed specification of proportional hazard models and their applications to reliability and availability of standby systems, see Refs 20 and 22.

Proportional hazard models are the simplest models for representing dependent-correlated events such as the standby. Anyway, other different and more complex forms of correlation can be used for representing dependent events (copula-based models, Marshall–Olkin models, and variants). The reader is directed to Chapter 8 of Ref. 23 for an overview of such models.

Coming back, suppose we apply the proportional hazard model of Equation (1) to a standby system initially in fully operating mode, the system hazard rate of the first change point (operating sleep mode switch at time y) is

$$h_y(t) = \begin{cases} h_X(t), & t < y, \\ \beta h_X(t), & t \geq y, \end{cases} \quad (2)$$

where $h_X(t)$ and $\beta h_X(t)$ are the hazard rate of the system in fully operating and sleep modes, respectively. β is a constant weighting the impact of standby in terms of reliability and is known as *dormancy factor* [15] or *dependency rate* [16]. In standby systems, the values of β range from 0 to 1: $\beta = 0$ identifies cold standby and $0 < \beta < 1$ characterizes warm standby while, in case of hot standby, $\beta = 1$.

Given the CDF of the trigger event $YF_Y(y)$, $h_X(t)$, and β , the goal of this section is to provide an equation describing the unreliability CDF of the standby system $F_{X,Y}(t)$. Since given the hazard rate $h(t)$, the CDF $F(t)$ can be expressed as $F(t) = 1 - e^{-\int_0^t h(x) dx}$, and the PDF $f(t)$ is $f(t) = h(t)e^{-\int_0^t h(x) dx}$, by applying the law of total probability it is possible to obtain the following formula for

$F_{X,Y}(t)$:

$$\begin{aligned} F_{X,Y}(t) &= \int_{-\infty}^{+\infty} \Pr(X \leq t | Y = y) f_Y(y) dy \\ &= \int_0^t \Pr(X \leq t | Y = y) f_Y(y) dy \\ &\quad + \int_t^{+\infty} \Pr(X \leq t | Y = y) f_Y(y) dy \\ &= \int_0^t (1 - \Pr(X > t | Y = y)) f_Y(y) dy \\ &\quad + F_X(t) F_Y(y) \Big|_t^{+\infty}. \end{aligned} \quad (3)$$

In order to evaluate the term $\Pr(X > t | Y = y)$, it is necessary to observe that the standby system is firstly, till y , in the sleep mode, and then, at y , switches in the fully operating state. In terms of probability this represents a change point, in which the system lifetime changes its distribution from the standby ($F_X^S(t) = 1 - e^{-\beta \int_0^t h_X(x) dx}$) to the fully operating ($F_X^O(t) = 1 - e^{-\int_0^t h_X(x) dx}$) mode. Applying the *conservation of reliability principle* [24], it is possible to quantify such effect as time, into the *delay* τ , by obtaining the *time equivalent*, so that at change point y it has

$$R_X^S(y) = R_X^O(y + \tau) \longrightarrow \tau = R_X^{O-1}(R_X^S(y)) - y, \quad (4)$$

where $R(t) = \Pr(T > t) = 1 - F(t)$, assuming that the CDF $R_X^O(\cdot)$ is *strictly decreasing* and therefore *invertible*. It is important to remark that the time equivalent delay τ could also be negative, that means that the system at change point increases its hazard rate.

In this way, the probability $\Pr(X > t | Y = y)$ becomes

$$\begin{aligned} \Pr(X > t | Y = y) &= R_X^O(t + \tau) \\ &= R_X^O\left(t + R_X^{O-1}(R_X^S(y)) - y\right). \end{aligned} \quad (5)$$

By substituting this term in Equation (3), we have

$$\begin{aligned} F_{X,Y}(t) &= F_X^S(t)(1 - F_Y(t)) \\ &\quad + \int_0^t (1 - R_X^O) \left(t + R_X^{O-1} \left(R_X^S(y) \right) - y \right) \\ &\quad \times f_Y(y) dy. \end{aligned} \quad (6)$$

The one reported in Equation (6) is a general formula valid for any type of standby. It could be of interest to characterize it for hot and cold standby. In the hot standby case, the system never changes its reliability, that is $R_X^O(t) = R_X^S(t) = R_X(t)$ (and obviously $F_X^O(t) = F_X^S(t) = F_X(t)$), thus it is expected that $F_{X,Y}^{HS}(t) = F_X(t)$. In order to verify Equation (6) it is necessary to apply such a condition to this latter thus obtaining

$$\begin{aligned} F_{X,Y}^{HS}(t) &= F_X(t)(1 - F_Y(t)) \\ &\quad + \int_0^t (1 - R_X(t)) f_Y(y) dy \\ &= F_X(t)(1 - F_Y(t)) + F_X(t)F_Y(t) \\ &= F_X(t). \end{aligned} \quad (7)$$

A system in cold standby is initially inactive, thus its reliability is $R_X^S(t) = 1$ or $F_X^S(t) = 0$, and therefore

$$\begin{aligned} F_{X,Y}^{CS}(t) &= \int_0^t (1 - R_X^O(t - y)) f_Y(y) dy \\ &= \int_0^t F_X^O(t - y) f_Y(y) dy, \end{aligned} \quad (8)$$

that is the convolution among events X and Y as expected.

The formulas reported in Equations 6–8 are valid for any generally distributed CDF. In the particular case that the standby system lifetime is exponentially distributed, due

to the age/memory-less property of exponential CDF, Equation (6) becomes an *exponential polynomial*:

$$\begin{aligned} F_{X,Y}(t) &= (1 - e^{-\lambda_X^S t}) e^{-\lambda_Y t} + (1 - e^{-\lambda_Y t}) \\ &\quad - \int_0^t e^{-\lambda_X^O \left(t + (\lambda_X^S - \lambda_X^O) / \lambda_X^O y \right)} \lambda_Y e^{-\lambda_Y y} dy \\ &= (1 - e^{-\lambda_X^S t}) e^{-\lambda_Y t} + (1 - e^{-\lambda_Y t}) \\ &\quad - \lambda_Y \int_0^t e^{-\lambda_X^O t - (\lambda_X^S - \lambda_X^O + \lambda_Y) y} dy \\ &= (1 - e^{-\lambda_X^S t}) e^{-\lambda_Y t} + (1 - e^{-\lambda_Y t}) \\ &\quad - \frac{\lambda_Y}{\lambda_X^S - \lambda_X^O + \lambda_Y} e^{-\lambda_X^O t} \\ &\quad \times \left(1 - e^{-(\lambda_X^S - \lambda_X^O + \lambda_Y) t} \right). \end{aligned} \quad (9)$$

SUMMARY

Standby systems are of fundamental importance in actual technologies since they are a way of reducing the environmental impact, extending the systems' lifetime, and especially of reducing and optimizing costs. It is important to fix the concept of standby such that it identifies a specific condition that differs from the operating one. Here, such distinction is mainly investigated from the reliability perspective providing both the intrinsic, isolated viewpoint and the external, system reliability viewpoint. In this way, a standby system can be characterized as an up or down state according to the underlying physical process that therefore must be adequately evaluated before classifying the standby.

In technological fields, the concept of standby is strictly related to the power. According to the power consumption of a standby system, the standby state can be further characterized. Following the relationship between reliability and power, three types of standby can be characterized as hot, if the system in standby has the same power consumption and reliability distribution of the fully operating condition; warm, if the system in standby is partially powered and

consequently has higher reliability than in the operating state; and cold, if the system is not powered and therefore cannot fail from standby.

STATISTICAL ANALYSIS OF CALL-CENTER OPERATIONAL DATA: FORECASTING CALL ARRIVALS, AND ANALYZING CUSTOMER PATIENCE AND AGENT SERVICE

HAIPENG SHEN
Department of Statistics and
Operations Research,
University of North Carolina
at Chapel Hill, Chapel Hill,
North Carolina

Call centers are modern service networks in which agents provide services to customers via telephones. They have become a primary contact point between service providers and their customers. *Inbound* call centers take calls that are initiated by customers. Examples include phone operations that support reservation and sales for hotels, airlines, and car rental companies, as well as service centers of retail banks and brokerage firms. *Outbound* call centers initiate calls to outside parties, for example, those in organizations such as telemarketers, bill collection agencies, and marketing research and polling companies.

The increasing importance and complexity of call-center operations have rendered call centers into a fertile ground for academic research, both empirical and theoretical. Two survey papers [1,2] and an on-line bibliography [3] have well documented the current state of relevant research on call-center operations and directions for future research. This article focuses on statistical research about inbound call centers, in the areas of call arrival forecasting and analysis of customer patience and agent service times. There has been empirical research on call centers that is done outside the operations community and covers behavioral and psychological aspects [2] and human resource issues [4].

Brown *et al.* [5] described a simplified path that each call follows through a typical inbound call center. A customer calls the telephone number associated with

the center. Once connected, the customer usually first enters an interactive voice response unit (IVR) and identifies himself or herself. In the IVR, the customer can perform some self-service transactions, and sometimes conclude the service there. In case the customer still wants to speak with an agent, if an agent is available and is capable of performing the desired service, then the customer is connected to the agent to receive service immediately; otherwise, the customer joins an invisible queue of waiting callers and starts to wait. It is often the case that informational or noninformational announcements such as music, commercials, or updates about any progress in the queue are provide to the customer while waiting. Eventually, the customer is either served by an agent or becomes impatient and hangs up (i.e., abandons) before an agent is available to serve him or her. Sometimes, the customer may call again after getting a busy signal, or abandoning the system, or even finishing a service.

The above simple description suggests that call centers can be modeled as queueing systems. Call-center managers then use queueing models to manage their center operations, seeking to appropriately balance agent utilization and service quality according to quality of service measures such as *average speed of answer* (ASA) or *fraction of abandoning customers*.

Existing queueing models usually make specific theoretical assumptions about various system primitives, such as the call arrival process, service durations, or customer abandonment behavior. The classical Erlang-C queueing model, for example, makes three assumptions: (i) the call arrival process is Poisson; (ii) service durations are exponentially distributed; and (iii) customers never abandon the queue before getting served. The third assumption turns out to be a serious shortcoming for modeling call centers, because of the prevalence of customer abandonment in call centers. The more recent so-called Erlang-A model is a more realistic

model that explicitly takes into account abandonments but assumes the *time to abandonment* distribution is exponential [6].

Gans *et al.* [1] assert that “the modeling and control of call centers must necessarily start with careful data analysis.” The queueing models all involve certain parameters for the system primitives, for example, the Erlang-A model needs one to specify call arrival rates, service rates, and customer abandonment rates. To apply these models in practice, the associated parameters need to be estimated or forecasted through statistical analysis of historical call-center operational data. Furthermore, Brown *et al.* [5] showed that statistical analysis could be used to validate and calibrate queueing theoretical models.

Despite the importance of statistics, however, the empirical research on call centers remained very scarce until recently. The recent emerging growth, especially in the area of call forecasting, is primarily driven by increased access to call-center data and by widened recognition of the importance of empirical research.

This article aims to provide an introductory review of some empirical research about inbound call centers. It starts with a brief description of call-center operational data and an analysis tool, continues in the sections titled “Call Forecasting” and “Customer Patience and Agent Service Times” with general overviews of statistical research in call forecasting, and analysis of customer patience and agent service times respectively, and ends with a discussion of several directions for future research in the section titled “Future Challenges.”

CALL-CENTER OPERATIONAL DATA

Call-center workforce management systems (WFM) routinely collect call-center operational data. The data record the physical process by which calls are handled. For example, among many other things, they consist of the time stamps of the various stages that a call goes through and the associated operational variables for each stage, which provide necessary starting points for most of the empirical research reported below.

A collaborative team of operations management researchers and statisticians performed the first thorough statistical analysis of a (then) unique call-by-call operational database collected at a call center of a small Israeli bank [5]. The analysis finds that several common queueing model assumptions are rejected empirically; in addition, some queueing-theoretic results are shown to be robust against such violations while a few others are not. The data and an earlier empirical analysis are publicly accessible from the Service Enterprise Engineering (SEE) Center at the Technion.

One key lesson the team learned is that, for successful and comprehensive statistical analysis, one needs call-by-call (or transaction-by-transaction) data that record the detailed event-history of the individual calls. For example, the team used the call-by-call data to develop statistical models for the distributions of call arrivals, agent service times and customer patience, which, in turn, allows one to make rigorous and valid statistical inference, or identify interesting empirical observations. Unfortunately, in practice call centers typically only use the call-by-call data to calculate simple summary statistics for the calls that arrive within fixed intervals of time, often 15 or 30 min, and then discard the transaction-level data. As demonstrated in Ref. 5, the aggregated summaries are too simple to provide enough details for meaningful statistical modeling, several examples of which are discussed later.

In addition, the WFMs are designed to collect the operational data in an “engineering-efficient” way; hence the collected data in most cases are not directly amenable for statistical analysis. The experience of analyzing the pilot study helped the team to define and develop a *DATA MOdel for Call-Center Analysis* (DATA-MOCCA) [7]. The mission of the DATA-MOCCA project is to collect, preprocess, organize, analyze, and distribute transactional data from call centers. The core of DATA-MOCCA is a database system that is useful for the analysis of the call-by-call data that are gleaned from call centers’ telephone switches and information systems. The latest distributable implementation includes

two large databases, one of a medium sized US bank and the other of an Israeli telecom company, along with a user-friendly query engine, SEESTAT, that facilitates empirical exploration and statistical analysis of the data. A public version of SEESTAT can be downloaded from the Technion SEE Center.

CALL FORECASTING

Seventy percent of call-center operating expenses are salary costs for human resource [1]. Effective management of a call center requires its manager to match up the center resource with future workload during any planning period. The workload or *offered load* is defined to be the product of the call arrival rate and the mean service time of the arrivals. One can interpret workload as the expected time units of work that arrives to the system per unit of time. For example, consider a stationary 30-min interval during which the arrival rate is 4 and the mean service time is 15 min, then the workload to the system would be $4 \times 15/30 = 2$. The workload serves as a lower bound for the staffing level for an Erlang-C system, which does not allow blocking or abandonment. Ideally, for staffing purposes, a manager wants to forecast workload accurately. However, most of the existing research has focused on forecasting future call arrival rates, with the exception of Refs 5 and 8.

In this section, we first describe several common characteristics of call arrivals in the section titled “Common Characteristics of Call Arrivals”: time inhomogeneity, arrival rate uncertainty, and interday and intraday dependence. These features are observed empirically and are useful for developing effective forecasting methods. We then review existing call-forecasting methods in the section titled “Call-Forecasting Methods.”

Common Characteristics of Call Arrivals

In most inbound call centers, both the arrival rate of calls and the mix of types of calls entering the system vary over time. Call arrivals have both *predictable* and *unpredictable* components: over very short periods

of time, seconds or minutes, the numbers of arriving calls are viewed as stochastic and unpredictable, typically as some form of a Poisson process; however, over longer periods of time—hours, days, weeks, or months—the numbers of arrivals are traditionally viewed as more predictable (see Fig. 5 of Ref. 1 for a hierarchical view of arrival rates).

Call forecasting starts with historical call arrival data, which record the time stamps at which calls arrive to the center and their corresponding service types, in cases where different types of calls are handled by different groups of agents. The common practice in the literature is as follows: first, the center operating period is divided into short time intervals, usually 15 or 30 min, during which the arrival rates are assumed to remain constant; then, the raw data of arrival times are aggregated into numbers of arrivals within the short intervals. The collection of such aggregated call volumes for a given day is referred as the *intraday call volume profile* of that day [9].

Common call-center models and practice then assume that the intraday call volume profile is a realization from a time-inhomogeneous Poisson process, where the underlying arrival rate function varies across different intervals. Brown *et al.* [5] constructed a statistical test, and empirically validated the time-inhomogeneous Poisson assumption using the Israeli call-center data. In addition, they performed a statistical test and claimed that the arrival rate function remains random (or uncertain) given the available covariates of time-of-day, day-of-week, and type of service, and hence is hard to predict. A Poisson process with uncertain arrival rate is referred as a *doubly stochastic Poisson process*, or a *Cox process*.

The phenomenon of arrival rate uncertainty can be manifested empirically through the *overdispersion* of the call volumes during the same time interval across multiple days. Here overdispersion refers to the fact that the variance of the volumes is much larger than the mean. Note that, if the volumes were independent and identically distributed according to a Poisson random variable, then the variance would be equal to the mean. This phenomenon has been recognized before

by various authors. Maman [10] recently proposed a theoretical model for overdispersion in call centers and hospital emergency departments, and suggested procedures to empirically estimate the model parameters.

After some initial processing, historical call arrival data, or historical intraday call volume profiles, can be stored as a two-way data matrix, where each row corresponds to the intraday call volume profile for a particular day, and each column records the call volumes during a particular time interval across the days. Alternatively, one could concatenate all the intraday profiles one after another to form a single long profile.

Viewing the historical arrival data as a matrix, there exists a two-way dependence structure that is useful for forecasting future arrival rates. First, there is *interday dependence* among the call volumes across days. For example, Brown *et al.* [5], Shen and Huang [9], and Weinberg *et al.* [11] all reported empirical evidence of dependence within the time series of daily total call volumes. Such dependence can depend on seasonal factors such as day-of-week, month-of-year, and is helpful for forecasting arrival rates several days, weeks, or months ahead.

In addition, there is *intraday dependence* in that call volumes during different time intervals within a given day are positively correlated. For example, Avramides *et al.* [12] developed doubly stochastic Poisson models that reproduced three empirically observed features of call arrival data, *overdispersion*, *time-varying rate*, and *intraday dependence*. Intraday dependence makes it possible to perform within-day dynamic updating, for example, to adjust the forecasts for the afternoon arrival rates on the basis of the call volumes in the morning of the same day. This updating is operationally both feasible and beneficial. As shown in Refs 9, 11, and 13, within-day updating can substantially reduce the forecast error for the rest of the day, and it can be done as early as a couple of hours into the working day to still have a significant effect. In turn, operational benefits would follow from the ability to change agent schedules according to the updated forecast. For example, to adjust for a revised forecast, call-center managers may send people home early

or have them take training sessions or work on alternative tasks; or they may arrange agents to work overtime or call in part-time or work-from-home agents. There is some ongoing work that formulates stochastic programming models with recourse actions to actually quantify the practical benefits of within-day updating for scheduling agents, using real call-center data.

Call-Forecasting Methods

Early work on forecasting of call arrivals usually ignores intraday dependence, and focuses on interday dependence among daily total call volumes. Part of the reason is due to lack of relevant data. Forecasting is usually performed through time series forecasting methods such as using autoregressive integrated moving average (ARIMA) models. Transfer functions and exogenous variables are included to incorporate special effects such as advertisement, holidays, and sales promotion. In addition, only point forecasts for future arrival rates are produced. Workforce management in call centers traditionally assumes that these point forecasts are certain. However, the arrival rate uncertainty reported earlier in the section titled “Common Characteristics of Call Arrivals” suggests that the forecasted rates are not realized with probability one.

Recently, with the availability of call-by-call data, several important developments in the call-forecasting literature have been made [5,8,9,11,13–15] that take into account both interday and intraday dependence. The forecasting approaches can be roughly grouped into two categories: model-driven and data-driven. Most of the recent developments consider both point forecasts and distributional forecasts, which capture forecasting uncertainty.

Model-Driven Approaches. The model-driven approaches include Refs 5, 8, 11, 13, and 14. They start with various stochastic models of call arrivals, often as some variations of Poisson processes.

Both Brown *et al.* [5] and Weinberg *et al.* [11] model the call arrivals using a time-inhomogeneous Poisson process with a random rate function. In both papers, a

square-root transformation is first applied to the original arrival counts. The motivation is twofold: first, the square-rooted counts roughly have a constant variance; second, they are approximately normally distributed. Brown *et al.* [5] then build a multiplicative two-way mixed-effects model on the transformed counts. The square-root of the arrival rate for each interval is modeled as the product of the daily total of the square-rooted rates and the proportion of arrivals during that time interval. They then assume that the arrival proportion for each interval remains the same for different days of the week, and the daily total square-rooted rate can be forecasted using the total of the square-rooted counts of the previous day.

Weinberg *et al.* [11] extended the work of Brown *et al.* [5] to develop forecasting models for both day-to-day forecasting and within-day updating. As an example of the various forecasting methods, the statistical model proposed by Weinberg *et al.* [11] is presented below. Suppose N_{ij} is the number of arrivals during the j th time interval of the i th day, which is modeled as a Poisson random variable with a random rate λ_{ij} that depends on both day-of-week and time-of-day. A two-way multiplicative Bayesian model is then proposed as follows:

$$\begin{cases} x_{ij} = \sqrt{N_{ij} + 1/4} = \sqrt{\lambda_{ij}} + \epsilon_{ij}, \epsilon_{ij} \sim N(0, \sigma^2), \\ \sqrt{\lambda_{ij}} = y_i g_{d_i}(t_j), \\ y_i - \alpha_{d_i} = \beta(y_{i-1} - \alpha_{d_{i-1}}) + \eta_i, \eta_i \sim N(0, \phi^2), \\ \frac{d^2 g_{d_i}(t_j)}{dt_j^2} = \tau_{d_i} \frac{dw_{d_i}(t_j)}{dt_j}, \end{cases}$$

where t_j is the center of the j th time period, $g_{d_i}(\cdot)$ models the *smooth* intraday call arrival pattern that depends on day-of-week $d_i (= 1, \dots, 5)$, y_i is a random effect with an autoregressive structure adjusting for d_i , and $W_{d_i}(t)$ are independent Wiener processes with $W_{d_i}(0) = 0$, and $\text{var}\{W_{d_i}(t)\} = t$. The model essentially assumes that the time series of daily total square-rooted rates follows a first-order autoregressive model with day-of-week effect, and the arrival proportion changes smoothly across the time intervals and can depend on day-of-week. The authors then choose suitable prior distributions for

the model parameters, and develop a Markov chain Monte Carlo (MCMC) algorithm for parameter estimation and forecasting. They also propose a within-day learning algorithm to efficiently perform within-day updating of arrival rates.

Without using the square-root transformation, Shen and Huang [13] directly modeled the historical arrival count matrix as observations from a time series of inhomogeneous Poisson processes, where the time series dependence is across the sequence of days (or rows of the data matrix). The count matrix is then viewed as a multivariate Poisson time series with the dimension being the number of columns in the matrix, or the number of time periods within a day. The dimensionality of the time series is usually high, for example, a 17-h working day consists of 68 time intervals of 15 min each. Hence, the authors start with a Poisson factor analysis on the count matrix to achieve dimension reduction. The estimated factor score series are then modeled using univariate time series models. The forecasts of future factor scores are combined with the extracted factor loadings to yield forecasts of future arrival rate functions. Penalized Poisson regressions on the factor loadings are used to generate dynamic within-day updating of arrival rates.

Unlike in the previous papers, Aldor-Noiman *et al.* [8] considered a univariate response vector by concatenating the square-root-transformed daily volume profiles together. This “long” volume profile (instead of the “fat” count matrix analyzed in the earlier studies) is then modeled using a normal linear mixed-effects model that treats both day and period effects as random effects, both of which are assumed to have a first-order autoregressive correlation structure, and includes exogenous variables such as day-of-week and billing cycle information as fixed effects. A two-stage model estimation algorithm is proposed in order to avoid convergence issues. The authors consider the problem of forecasting both arrival rate as well as workload, under various forecast lead times. In addition, they study the effect of interval length on forecasting accuracy and

the effect of the model results on call-center operational performance.

Similar to Weinberg *et al.* [11], Soyer and Tarimcilar [14] also used a Bayesian approach to model call arrivals at an inbound sales call center. For the purpose of developing good marketing strategies, the authors are interested in advertisement-specific analysis of call arrivals to evaluate the efficiency of various advertisements and promotions. Different from the previous studies, the call arrival data are counts of incoming calls during periods of days over the life cycle of an advertisement. The counts are modeled using a modulated time-inhomogeneous Poisson process. A proportional rate model is used to model the underlying arrival rate function as the product of a baseline rate function and an advertisement effect consisting of exogenous variables such as the advertisement characteristics. Similar models have been considered before in the survival analysis literature. Random effects are used to incorporate potential heterogeneity among various advertisements.

Data-Driven Approaches. The data-driven forecasting approaches include Refs 9 and 15. The approaches have advantages in cases where no specific stochastic models for the call arrival processes are made. For example, there exists empirical evidence that calls entering the service queue after a congested IVR did not follow a time-inhomogeneous Poisson process.

Shen and Huang [9] combine the ideas of dimension reduction and time series forecasting; hence the method is similar to the one proposed by them in Ref. 13. Two differences between Refs 9 and 13 are (i) the former does not make any assumption on the arrival process, while the latter assumes that the call arrivals follow a time-inhomogeneous Poisson process; (ii) the former produces forecasts for future call volumes while the latter generates future rate forecasts. The authors [9] treat the square-rooted intraday call volume profiles as a high dimensional vector time series. They first reduce the dimensionality by applying singular value decomposition to the square-rooted count matrix. The dimension reduction allows

them to obtain several pairs of “most important” interday and intraday features, which naturally decouple interday and intraday dependence. Once these features are obtained, in a manner similar to Ref. 13, time series models and penalized regression techniques are used to perform interday forecasting and intraday updating. Since no distributional assumptions are made on the arrival counts, nonparametric bootstrapping is proposed to derive distributional forecasts.

Similar to Aldor-Noiman *et al.* [8], Taylor [15] views the historical data as a “long” univariate time series, and compares the empirical performance of several univariate time series methods for forecasting intraday call arrivals. The methods studied include seasonal ARIMA time series models, periodic autoregressive models, exponential smoothing models with two seasonal cycles (for intraday and intraweek), robust exponential smoothing, and dynamic harmonic regression. The author focuses on point forecasting, and considers forecasting lead times ranging from one half-hour ahead to two weeks ahead. No clear winning method is identified, although seasonal ARIMA and exponential smoothing with two seasonal cycles appear to perform better for lead times up to two days ahead.

CUSTOMER PATIENCE AND AGENT SERVICE TIMES

Call-center operations are complicated partly due to the human factors involved in particular, customers and agents. In call centers, it is people, rather than “jobs,” that require service and it is people, rather than equipments, that provide the service. Call-by-call operational data also provide opportunities for researchers to empirically study customer and agent behaviors in a call-center environment. Although research in this area is still lacking, interesting and important developments have been made recently. The review below focuses on statistical analysis of customer patience and agent service times.

Customer Abandonment and Patience

As discussed earlier, for customers who want to speak with agents, chances are that they

need to wait in the service queue before getting served. Some of them will become impatient, and abandon the system before an agent becomes available. Hence, it is important to understand customer abandonment or patience behavior. In addition, a wrong model of customer patience can lead to wrong staffing [16].

Traditional queueing theory has been naive in its modeling of customer patience, which is often ignored. If at all acknowledged, customers are usually assumed to arrive to the system with independent and identically distributed patience. Furthermore, the patience distribution is most often assumed to be exponential as in the Erlang-A model [6].

Brown *et al.* [5] analyze customer patience empirically at the Israeli call center. They propose to use *the time that a customer is willing to wait before hanging up* as an ancillary measure for the customer's patience. Note that this measure is observed only for a customer who does hang up. For a customer who gets served, we only know that he or she is willing to wait longer than his or her actual waiting time; however, we do not know exactly how much longer, in which case his or her patience is considered to be *right censored*. For statistical analysis of customer patience, the censoring has to be dealt with using survival analysis techniques.

Several interesting empirical observations are revealed by the analysis. First, a clear stochastic ordering emerges among customers seeking different services. For example, stock-trading customers are more patient than customers seeking regular services. Similarly, high priority customers appear to be more patient than regular customers [1]. Second, customers are more likely to abandon the queue after waiting for either only a few seconds or about 60 s. One plausible explanation is that the call-center system plays a "Please wait" message after a customer waits a few seconds and again at 1 min, which apparently prompts the customers to abandon the queue. This also suggests that the patience distribution is not exponential. If it were, the probability for a customer to abandon would remain the same, no matter how long she had waited.

Furthermore, the authors demonstrate empirically that the Erlang-A model is very robust against the violation of the exponential assumption of customer patience. The observation of the robustness motivates further research to explore for theoretical justification, which is later provided by Zeltyn and Mandelbaum [16].

Adaptivity of Customer Patience

Traditional queueing theory also assumes that customer patience is independent of system performance, unrelated to past experience or future anticipation of the system. However, Zohar *et al.* [17] provide some empirical evidence to support an inconsistent hypothesis: experienced customers "adapt" their patience on the basis of their expectations regarding system waiting time.

Using the Israeli call-center data, for every 15-min interval during weekdays between 7.00 a.m. and midnight, the *percentage of abandonment* of those customers who wait as well as the *average waiting time* for the same customers are calculated. Surprisingly, for experienced customers, the percentage of abandonment remains at about 38%, regardless of what the average waiting time is, which ranges between 90 and 250 s; on the other hand, for novice customers, the two measures are strongly positive linear dependent. In addition, for experienced customers, the expected patience increases linearly when the system is more congested (and hence needs the customers to wait longer). This also suggests that the experienced customers know what to expect on the basis of their past experience, and when the system needs them to wait longer, they are willing to do so.

Agent Service Times

As providers of service to customers via telephones, call-center agents are another important human component of call-center operations. However, even less empirical research has been devoted to study them.

Traditionally, queueing models assume that service times within a given interval are independent and identically distributed according to an exponential distribution. This

assumption is imposed mainly for theoretical simplicity due to the lack-of-memory property of exponential distributions. Although some empirical evidence exists for the exponentiality, service times are not always exponentially distributed. For example, Brown *et al.* [5] analyze the individual call service times in the Israeli call center, and show that they are lognormally distributed, that is, their natural logs are normally distributed. This fact makes the natural logs appealing for statistical analysis. Furthermore, the lognormal distribution provides an excellent fit not only for the overall service time but also when restricted to service types, individual agents, time-of-day, and so on.

Using the call-by-call data, the authors also find out that, in the early portion of the data, a significant amount of calls (7%) are handled in less than 10 s, comparing to 2% of such calls during the latter portion. Service times shorter than 10 s are questionable. As a matter of fact, those short service times are primarily caused by agents who simply hang up on customers to obtain extra rest time. This phenomenon of agents “abandoning” customers is often due to distorted incentive schemes, especially those that overemphasize short average service time or the total number of calls handled by an agent.

FUTURE CHALLENGES

We conclude this article with a brief discussion of several challenging research problems. Empirical analysis of call-by-call operational data should shed light on all of them, influencing how they are modeled by researchers, as well as how they are managed in practice.

The first challenge is about workload forecasting. Most research reviewed in the section titled “Call Forecasting” focuses on forecasting future arrival rates. However, to support agent staffing, a call-center manager requires forecasts of future workload, which combines arrivals with the service times of these arrivals. This is an important but difficult problem for time-varying arrivals, because there exists a time lag between peak arrivals and peak congestion [18].

More work is needed to develop methods that forecast arrival rates and service rates simultaneously. Some interesting contribution has been made recently at the Technion, where a procedure is proposed to estimate the service-time distribution of those abandoning customers.

The second challenge concerns the use of IVRs, which enable customers to use self-service without speaking to an agent. Little is formally known about the statistical or operational properties of IVRs and how they should be managed. At a high level, customer interaction with an IVR can be thought of as a service time, to which queueing-theoretic concepts can be applied. However there has been very limited theoretical work on the use of IVRs. To summarize, the time a customer spends in the IVR, as well as how that time affects subsequent agent service time, are important elements of call-center operations about which little is known.

The third challenge has to do with customer retrieval behavior. More specifically, many of the impatient abandoning customers then become so-called retrials, calling again at a later time. Similarly, customers that receive busy signals, as well as those that are served, may become retrials. While there are classical theoretical models of retrieval queues, again little is known about the actual retrieval behavior of customers. Careful analysis of retrieval data should help to shape how retrials are modeled and managed in the future. Some ongoing research at the Technion is analyzing customer retrials using frailty models.

The analyses of IVRs and customer retrials are interesting in and of themselves. They are also important because of their potential impact on the statistical properties of the stream of calls that arrives to agents. Both IVR and retrieval behavior have the potential to change important statistical properties of the pattern of arrivals to agents. For example, the calls exiting a congested IVR may not be Poisson.

While waiting, customers usually listen to music, commercials, or updates of their positions in the queue. These messages are referred to as *waiting-time fillers* in consumer psychology. How customers react to such

time fillers is another important but under-explored research problem. Brown *et al.* [5] observe empirically that a “Please wait” message actually prompts customers to hang up. Recently, Munichor and Rafaeli [19] used lab experiments to study caller reactions to three types of telephone waiting-time fillers: music, apologies, and information about location in the queue. On the basis of the callers’ evaluations after getting their services, the authors conclude that callers are happier when they are given a sense of progress through periodic updates of their position in the queue.

Furthermore, a better empirical understanding of service-time heterogeneity is needed. Empirical research has shown that differences among service times are associated with service types and time-of-day. There is much more work that could and should be done to better understand the drivers of service times. For example, it is interesting to understand how the heterogeneity is caused by agent-specific factors such as learning, forgetting, shift fatigue, and cross-training. Such research findings can complement and benefit recent theoretical work addressing agent heterogeneity in call centers.

Finally, the existence of heterogeneous customer classes and agent types and the employment of skills-based routing introduce additional complications and present many interesting questions. For example, in the context of workload prediction, the prediction depends in some sense on how customers are routed to agents; if one routes more customers to the slow agents, then the workload will be higher. Skills-based routing decisions also affect customers’ waiting experience and their patience.

STATISTICAL METHODS FOR OPTIMIZATION

L. JEFF HONG

Technology, Clear Water Bay,
Hong Kong, China

INTRODUCTION

In this chapter, we consider the following stochastic optimization problem

$$\text{maximize } \{g(\mathbf{x}) = \mathbb{E}_{\mathbf{x}} [Y(\mathbf{x})]\}, \quad \mathbf{x} \in \Theta \subset \mathbb{R}^d, \quad (1)$$

where $\mathbf{x}$ is the vector of decision variables (also called a solution) in $\mathbb{R}^d$ and Y is a random variable whose distribution depends on $\mathbf{x}$. In other words, we try to maximize an objective function that is defined as the expected value of a random variable whose distribution depends on the decision variable $\mathbf{x}$. To evaluate the objective function, we can only run experiments at a particular value of $\mathbf{x}$. In this article, we only consider simulation experiments that are conducted in a computer. The output of an experiment is only a realization of $Y(\mathbf{x})$. Furthermore, the distribution of the output may vary significantly over the feasible region, and little is known about its properties (e.g., differentiability and convexity) of the (implied) objective function.

Depending on the structures of the solution $\mathbf{x}$ and feasible region Θ , many statistical methods have been proposed to solve Problem 1. When Θ is a continuous subset of $\mathbb{R}^d$, we may solve the problem using stochastic approximation algorithms or response surface methodologies; when $\mathbf{x}$ is discrete and integer ordered, $|\Theta|$ may be large or even infinite and we may use random search algorithms. All these methods are introduced in

other articles in this encyclopedia. In this article, we focus on the ranking and selection (R&S) problem, where Θ has a small number of solutions (often less than 500); we may simulate all solutions and select the best among them.

Many practical problems can be formulated as an R&S problem. Here are some examples:

- choice of product variants to stock in inventory to maximize expected profit when demands are stochastic;
- allocation of buffer capacity along an auto assembly line to minimize the sum of work-in-process of all stations;
- determination of the number of automatic guided vehicles (AGVs) to balance the investment in AGVs and the average storage-and-retrieval time of a material handling system.

R&S problems are classical statistical problems. They have been studied extensively in the statistics and simulation literature. For a more comprehensive review of the topics, readers are referred to the monograph of Bechhofer *et al.* [1] and the review article by Kim and Nelson [2].

BASIC FORMULATIONS

Suppose that there are totally $k \geq 2$ solutions in Θ , denoted as $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k$. We let $Y_j(\mathbf{x}_i)$ denote the j th observation from simulating solution $\mathbf{x}_i$, and assume that $Y_j(\mathbf{x}_i)$ follows a normal distribution of mean $g(\mathbf{x}_i)$ and variance σ_i^2 , where $g(\mathbf{x}_i)$ is unknown. Then, solving Problem 1 is equivalent to selecting the solution among $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k$ that has the largest mean. To further simplify the notation, we let $\mu_i = g(\mathbf{x}_i)$ and $Y_{ij} = Y_j(\mathbf{x}_i)$. Without loss of generality, we let $\mu_k \geq \mu_2 \geq \dots \geq \mu_1$ and the goal is to find which solution is $\mathbf{x}_k$.

Because Y_{ij} , $i = 1, \dots, k$, are normal random variables, no statistical methods

can guarantee to find the best solution with probability 1 using a finite number of observations. Therefore, all R&S procedures can only guarantee to find the best solution with a certain predetermined and large probability $1 - \alpha$, where α is often set to 0.1, 0.05 or 0.01.

Furthermore, because the difference between μ_k and μ_{k-1} can be arbitrarily close to zero, it imposes both theoretical and practical difficulties on the problem. Theoretically, without knowing the difference between μ_k and μ_{k-1} , it is difficult to decide the (finite) sample sizes for all solutions that guarantee to identify $\mathbf{x}_k$ with a probability $1 - \alpha$. Practically, if μ_k and μ_{k-1} are close to each other, it may require a large amount of simulation effort to differentiate them. In many practical situations, however, we may think both $\mathbf{x}_k$ and $\mathbf{x}_{k-1}$ are acceptable if their means are close to each other and hence, the effort is essentially wasted. To resolve these difficulties, two formulations were proposed to soften the goal of finding $\mathbf{x}_k$ with a probability $1 - \alpha$. In the first formulation, the goal is softened to finding a subset of solutions that contains $\mathbf{x}_k$, which is known as the “subset selection formulation”. In the second formulation, the goal is softened to finding $\mathbf{x}_k$ if $\mu_k - \mu_{k-1} \geq \delta$, which is known as the “indifference-zone (IZ) formulation”.

SUBSET-SELECTION FORMULATION

The subset selection formulation was proposed by Gupta [3]. It supposes that there are $n_i > 0$ i.i.d. observations from solution $\mathbf{x}_i$ for all $\mathbf{x}_1, \dots, \mathbf{x}_k$. The goal is to use these data to obtain a subset $I \subset \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k\}$ such that

$$\Pr\{\mathbf{x}_k \in I\} \geq 1 - \alpha. \quad (2)$$

As an example of a subset selection procedure, we consider the classical Gupta’s procedure, where each solution has n observations, $\sigma_1^2 = \dots = \sigma_k^2 = \sigma^2$, and σ^2 is known.

Gupta’s Procedure.

Step 1. Determine the constant h , which satisfies $\Pr\{Z_i \leq h, i = 1, 2, \dots, k-1\} =$

$1 - \alpha$ where $(Z_1, Z_2, \dots, Z_{k-1})$ have a multivariate normal distribution with means 0, variances 1, and common pairwise correlations $1/2$.

Step 2. For all $i = 1, 2, \dots, n$, calculate $\bar{Y}_i(n) = \frac{1}{n} \sum_{j=1}^n Y_{ij}$.

Step 3. Let the set I include all solutions $\mathbf{x}_\ell$ such that

$$\bar{Y}_\ell(n) \geq \max_{i \neq \ell} \bar{Y}_i(n) - h\sigma\sqrt{2/n}. \quad (3)$$

Note that

$$\begin{aligned} \Pr\{\mathbf{x}_k \in I\} &= \Pr\left\{\bar{Y}_k(n) \geq \bar{Y}_i(n) - h\sigma\sqrt{\frac{2}{n}}, \right. \\ &\quad \left. i = 1, 2, \dots, k-1\right\} \\ &= \Pr\left\{\frac{\bar{Y}_i(n) - \bar{Y}_k(n) - (\mu_i - \mu_k)}{\sigma\sqrt{2/n}} \right. \\ &\quad \left. \leq h - \frac{\mu_i - \mu_k}{\sigma\sqrt{2/n}}, i = 1, 2, \dots, k-1\right\} \\ &\geq \Pr\{Z_i \leq h, i = 1, 2, \dots, k-1\} \\ &= 1 - \alpha, \end{aligned} \quad (4)$$

where Equation (4) follows from the facts that $\mu_i - \mu_k \leq 0$ and $\bar{Y}_i(n) - \bar{Y}_k(n)$ is a normal random variable with mean $\mu_i - \mu_k$ and variance $2\sigma^2/n$ for all $i = 1, \dots, k-1$. Therefore, Gupta’s procedure is valid, that is it guarantees Equation (2).

Gupta’s procedure includes many of the elements that are essential to a subset selection procedure. It determines the screening criteria, that is Equation (3), based on the variances of the solutions and the fact that $\mu_i - \mu_k \leq 0$ for all $i = 1, \dots, k-1$. At the end of the procedure, it gives a subset that contains the optimal solution $\mathbf{x}_k$ with a probability greater than or equal to $1 - \alpha$. However, there is no guarantee on the size of the subset. It may contain multiple solutions.

INDIFFERENCE-ZONE FORMULATION

The IZ formulation was proposed by Bechhofer [4]. It supposes that $\delta > 0$ is the smallest difference that the experimenter feels

is worth detecting, where δ is known as the IZ parameter. The goal is to guarantee that

$$\Pr\{\text{selecting } \mathbf{x}_k\} \geq 1 - \alpha \quad (5)$$

if $\mu_k - \mu_{k-1} \geq \delta$.

As an example of an IZ selection procedure, we consider the classical Bechhofer's procedure, where each solution has n observations, $\sigma_1^2 = \dots = \sigma_k^2 = \sigma^2$, and σ^2 is known.

Bechhofer's Procedure.

Step 1. Determine the constant h , which is the same as the one in Gupta's procedure. Let

$$n = \left\lceil \frac{2h^2\sigma^2}{\delta^2} \right\rceil.$$

Step 2. Take n i.i.d. observations from each solution and calculate $\bar{Y}_i(n)$ for all $i = 1, 2, \dots, k$.

Step 3. Select the solution with the largest sample mean $\bar{Y}_i(n)$ as the best.

Note that

$$\begin{aligned} & \Pr\{\text{selecting } \mathbf{x}_k\} \\ &= \Pr\{\bar{Y}_k(n) \geq \bar{Y}_i(n), i = 1, 2, \dots, k-1\} \\ &= \Pr\left\{\frac{\bar{Y}_i(n) - \bar{Y}_k(n) - (\mu_i - \mu_k)}{\sigma\sqrt{2/n}} \leq -\frac{\mu_i - \mu_k}{\sigma\sqrt{2/n}}, i = 1, 2, \dots, k-1\right\} \\ &\geq \Pr\{Z_i \leq h, i = 1, 2, \dots, k-1\} \quad (6) \\ &= 1 - \alpha, \end{aligned}$$

where Equation (6) follows from the fact that $\mu_k - \mu_i \geq \delta$ for all $i = 1, \dots, k-1$. Therefore, Bechhofer's procedure is valid, that is, it guarantees Equation (5).

Bechhofer's procedure includes many of the elements that are essential to an IZ selection procedure. It determines the sample sizes required for all k solutions based on the variances of the solutions and the

fact that $\mu_k - \mu_i \geq \delta$ for all $i = 1, \dots, k-1$. At the end of the procedure, it selects the solution with the largest sample mean after all solutions acquired the required number of samples. Furthermore, because the procedure is designed for the least favorable configuration (LFC), where $\mu_k - \mu_i = \delta$ for all $i = 1, \dots, k-1$, it is typically conservative, achieving a probability of correct selection of more than $1 - \alpha$, when the configuration of the solutions is not the LFC.

DESIGNING R&S PROCEDURES FOR COMPUTER EXPERIMENTS

Classical R&S procedures were designed for real experiments, for example agricultural or pharmaceutical experiments, which often take a long time to complete. When solving Problem (1), however, we typically consider computer experiments that can be completed in minutes or even seconds. The nature of computer experiments introduces some new features to R&S problems. In this section, we consider several of these features and discuss how R&S procedures may take these features into consideration.

UNKNOWN AND UNEQUAL VARIANCES

Both Gupta's and Bechhofer's procedures assume that variances are known and equal. When conducting computer experiments, however, we often explore a relatively large number of solutions which may differ significantly. The assumption of equal known variances is no longer reasonable. Much work has been done to relax this assumption and to allow unknown and unequal variances.

For subset selection procedures, samples from all solutions are available before applying the procedure. Therefore, one may use these samples to estimate the variances first and then use the estimated variances to determine a screening criterion. Note that when variances are estimated, procedures need to be modified or adjusted so that they account for the variability of estimated variances. The procedure of Boesel *et al.* [5] is an

example of such a procedure. It first calculates the sample variances S_i^2 , where

$$S_i^2 = \frac{1}{n_i - 1} \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_i)^2$$

for all $i = 1, \dots, k$. It then includes in the subset all $x_i, i = 1, \dots, k$, such that

$$\bar{Y}_i(n_i) \geq \max_{j \neq i} \left\{ \bar{Y}_j(n_j) - \left(t_i^2 \frac{S_i^2}{n_i} + t_j^2 \frac{S_j^2}{n_j} \right)^{1/2} \right\},$$

where $t_i = t_{(1-\alpha)^{1/(k-1)}, n_i-1}$ is the $(1-\alpha)^{1/(k-1)}$ -quantile of a t -distribution with $n_i - 1$ degrees of freedom.

For IZ selection procedures, one needs to determine the sample sizes for all solutions based on the variances. Therefore, all of these procedures need a first stage to collect some samples from every solution to estimate the variances. They then use the estimated variances to determine the sample size of every solution in the second stage. After collecting the second-stage samples, the procedures select the solution with the largest overall sample mean, calculated from both the first- and second-stage samples. Rinott's procedure [6] is an example of such a procedure. In the first stage, it takes n_0 samples from all solutions, calculates their sample variances S_i^2 , and determines the final sample sizes

$$N_i = \max \left\{ n_0, \left\lceil \frac{h^2 S_i^2}{\delta^2} \right\rceil \right\}$$

for all $i = 1, \dots, k$, where h is a constant that solves Rinott's integral for n_0, k , and α ([7]). In the second stage, it takes $N_i - n_0$ samples from $\mathbf{x}_i$ and selects the solution with largest $\bar{Y}_i(N_i)$.

COMMON RANDOM NUMBERS

All procedures considered so far use independent samples for different solutions. However, it is not necessary. The randomness in computer experiments is created by using pseudorandom numbers [8]. This allows the experimenter to use the same stream of pseudorandom numbers for all solutions and thus, to introduce positive correlations between

$Y_{i\ell}$ and $Y_{j\ell}$, and to sharpen the comparisons between any pair of solutions $\mathbf{x}_i$ and $\mathbf{x}_j$ (for instance, the examples 14.10 and 14.11 in Ref. 9 show that common random numbers (i.e., CRNs) can lead to dramatic data savings).

When common random numbers are used, we typically calculate the sample variances S_{ij}^2 of $Y_{i\ell} - Y_{j\ell}$ for all $i \neq j$ and use the variances to conduct subset selection or IZ selection. As an example, we consider Clark and Yang's IZ selection procedure [10]. The procedure first takes n_0 observations from all solutions in the first stage, calculates the sample variances

$$S_{ij}^2 = \frac{1}{n_0 - 1} \sum_{\ell=1}^{n_0} \left[(Y_{i\ell} - Y_{j\ell}) - (\bar{Y}_i(n_0) - \bar{Y}_j(n_0)) \right]^2$$

for all $i \neq j$, and computes the final sample size

$$N = \max \left\{ n_0, \max_{i \neq j} \left\lceil \frac{t^2 S_{ij}^2}{\delta^2} \right\rceil \right\},$$

where $t = t_{1-\alpha/(k-1), n_0-1}$. In the second stage, it takes $N - n_0$ samples from all x_i and selects the solution with largest $\bar{Y}_i(N)$. The procedure ensures its validity by using the Bonferroni inequality that is typically very conservative when the number of solutions is large. Nelson and Matejcek [11] also considered this problem for equal-variance cases. They introduced the concept of sphericity to avoid using the Bonferroni inequality.

SEQUENTIAL NATURE OF COMPUTER EXPERIMENTS

In many real experiments, samples are taken in a batch. For instance, when testing the effectiveness of a drug, a sample of n patients may take the drug at the same time. It is often not practical to give the drug to only one patient at a time and wait to see the result before giving the drug to another. However, computer experiments are often conducted on just a single computer. Then, the samples are taken one at a time. In this situation, it makes sense to conduct subset selections

sequentially until only one solution remains in the subset. This is essentially the basic idea behind many sequential IZ selection procedures.

Many of the sequential IZ selection procedures were designed based on a Brownian motion approximation. Let

$$Z_{ij}(n) = \frac{n}{\sigma_{ij}^2} [\bar{Y}_i(n) - \bar{Y}_j(n)],$$

where $\sigma_{ij}^2 = \text{Var}(Y_{i\ell} - Y_{j\ell})$, which is $\sigma_i^2 + \sigma_j^2$ if $Y_{i\ell}$ and $Y_{j\ell}$ are independent, and let $\mathcal{B}_\Delta(t)$ denote a Brownian motion process with a drift Δ evaluated at time $t > 0$. Then, one can show that $Z_{ij}(n), n = 1, 2, \dots$, have the same joint distribution as $\mathcal{B}_{\mu_i - \mu_j}(n/\sigma_{ij}^2), n = 1, 2, \dots$

Given the Brownian motion approximation, we can then apply the results of Brownian motion process to design sequential IZ selection procedures. An oft-used result is the Fabian's bound [12]. Let Λ denote a triangular continuation region formed by $-a + \lambda t$ and $a - \lambda t$, where $a > 0, \lambda = \Delta/2 > 0$ and $t \geq 0$. Let $T = \inf\{t > 0 : \mathcal{B}_\Delta(t) \notin \Lambda\}$, T is the random time that $\mathcal{B}_\Delta(t)$ first exists Λ . Then, Fabian [12] showed that

$$\Pr\{\mathcal{B}_\Delta(T) < 0\} = \frac{1}{2} e^{-a\Delta}. \quad (7)$$

Note that it is the probability that a Brownian motion process with a positive drift Δ exists in the triangular continuation region from the negative side.

The KN procedure of Kim and Nelson [13] uses Equation (6) to select appropriate triangular region parameters (a, λ) to ensure the probability of correct selection. Suppose that $\mathbf{x}_i$ remains until the $n - 1$ sample. Then, after taking an additional sample for every remaining solution, $\mathbf{x}_i$ will be eliminated if

$$\frac{n}{S_{ij}^2} [\bar{Y}_i(n) - \bar{Y}_j(n)] < -a + \lambda \frac{n}{S_{ij}^2}$$

for any remaining $\mathbf{x}_j$. Note that the elimination criterion corresponds to the existing triangular region from the negative side if $\mu_i - \mu_j \geq \delta$. The KN procedure allows the use of common random numbers, is statistically

valid, and is much more efficient than typical two-stage procedures, especially when some of the differences between μ_k and $\mu_i, i = 1, \dots, k - 1$, are significantly larger than δ . Kim and Nelson [14] extended the procedure to allow weak dependence among the samples that are taken from the same solution. Batur and Kim [15] designed a fully sequential IZ procedure with a continuation region that is formed by parabolic boundaries.

Hong [16] further extended the Brownian motion approximation and showed that

$$Z_{ij}(m, n) = \left(\frac{\sigma_i^2}{m} + \frac{\sigma_j^2}{n} \right)^{-1} [\bar{Y}_i(m) - \bar{Y}_j(n)]$$

and $\mathcal{B}_{\mu_i - \mu_j} \left(\left(\sigma_i^2/m + \sigma_j^2/n \right)^{-1} \right)$ have the same joint distribution. This result can be used to design sequential IZ selection procedures that allows different sample sizes for different solutions. It is especially helpful when σ_i^2 and σ_j^2 are significantly different.

SAMPLING VERSUS SWITCHING

Typical fully sequential IZ selection procedures, such as the KN procedure, take a sample at a time from every remaining solution and reduce the total sampling cost by allowing early termination. It also requires repeated switching among the computer models of different solutions. Unfortunately, the computational overhead of switching can be significant, sometimes orders of magnitude more than that of sampling. Therefore, these sequential procedures may actually be slower than the two-stage procedures (e.g., Rinott's procedure) that require at most $2k$ switchings, even though they may require a smaller number of samples to make the selection decision.

To design sequential selection procedures that account for switching costs, Hong and Nelson [17] proposed two strategies. In both strategies, the procedures have a first stage that estimates the sample variances of all solutions, computes the parameters of the continuation region, and decides the maximal sample size that a solution may have before the selection decision is made. In the

first strategy, which is known as the *minimum switching strategy*, the procedure sorts the first-stage sample means and allocates the maximal sample size to the solution with the highest first-stage sample mean. It then allocates one sample at a time to the second-best solution and compares the second-best with the best to see if either one may be eliminated. If the second-best is eliminated, the best remains to be the current best; otherwise, the second-best becomes the current best and we allocate the maximal sample size to it. Then, we take a sample at a time from the third-best, compare it to the current best, and so on until only one solution remains. We declare the remaining solution as the best solution. In this strategy, the current sample best solution always gets the maximal sample size and we switch at most k times after the first stage (which switches k times). Therefore, it has a minimal $2k$ switchings. In the second strategy, Hong and Nelson [17] suggested using dynamic decision making for the number of switchings, based on the sampling and switching costs.

To implement both strategies, Hong and Nelson [17] design sequential IZ selection procedures based on Fabian's bound. Osogami [18] further extended the minimal switching procedure and used Anderson's bound instead of Fabian's bound, and the resultant procedure is more efficient than the one used by Hong and Nelson [17].

LARGE NUMBER OF SOLUTIONS

In many optimization problems, the number of solutions may be large. In such a case, IZ selection procedures are typically not very efficient. When the number of solutions is large, the differences between the best solution and some of the not-so-good solutions can be quite large. Then, these solutions may be easily eliminated by a subset selection procedure.

Nelson *et al.* [19] proposed a decomposition approach that uses a subset selection in the first stage to screen out clearly inferior solutions and applies an IZ selection to select the best solution in the second stage. They showed that, if the first stage has an error probability α_1 and the second stage

has an error probability α_2 , the error probability of the entire procedure is bounded above by $\alpha_1 + \alpha_2$. Therefore, to ensure that the procedure selects the best solution with a probability at least $1 - \alpha$, they suggested designing both stages with a $1 - \alpha/2$ probability of correct decision and developed such a procedure.

As we mentioned in the section titled "Sequential Nature of Computer Experiments," sequential procedures are much more efficient than typical two-stage procedures when there are clearly inferior solutions. Therefore, they also work well when the number of solutions is large.

EMBEDDING R&S IN OTHER OPTIMIZATION ALGORITHMS

To use R&S procedures to solve stochastic optimization problems, all solutions need to be sampled and compared. When the number of solutions is very large (or even infinite), R&S procedures become infeasible. However, many other stochastic optimization algorithms can solve such problems. The basic idea of many such algorithms is to use problem structure to gradually find the optimal solution by evaluating only a small fraction of the solutions. In this subsection, we summarize methods that embed R&S procedures in different levels of those algorithms to improve their performances.

Boesel *et al.* [5] proposed the "cleanup" idea, which applies an R&S procedure at the end of the optimization process to select the best solution among all solutions that are visited by the optimization algorithm. Because an optimization algorithm may visit many solutions before it stops, their procedure implements the decomposition approach of the previous section, uses the subset selection procedure of the section titled "Unknown and Unequal Variances" to screen out clearly inferior solutions by using the samples collected in the optimization process, and then applies a Rinott-type procedure of the same section to select the best solution. Their procedure guarantees that the solution found at the end is the best solution among all visited solutions with a probability of at least $1 - \alpha$.

Many optimization algorithms compare the solutions from a neighborhood and select

the best one. Pichitlamken *et al.* [20] proposed a sequential selection procedure to conduct this neighborhood selection. Their procedure takes into the consideration of the fact that in the neighborhood selection problem, different solutions may have different numbers of samples and only the sample means of those solutions may be available. They showed that their procedure achieves the required probability of correct selection under the typical IZ formulation and works well when embedded in optimization algorithms. Similar to the neighborhood selection problem, Xu *et al.* [21] proposed a sequential procedure that tests the local optimality of a solution among its neighboring solutions.

In the optimization process, the solutions are visited sequentially and we often do not know in advance how many solutions the algorithm will visit. This imposes a difficulty in the design of selection procedures, because the number of solutions (k) is often a necessary design parameter. Hong and Nelson [22] proposed two strategies to solve this problem of not knowing k in advance: the single-elimination strategy and the stop-and-go strategy. In the first strategy, a solution that is eliminated will not be considered again. In the second strategy, an eliminated solution will be considered again after more solutions are visited. Hong and Nelson [22] designed statistically valid fully sequential procedures to implement both strategies.

So far, we have only considered those optimization problems where the randomness exists only in the objective function. In many optimization problems, however, there is also randomness in the constraints. Then, identifying the feasibility of a solution is as important as selecting the best solution. Batur and Kim [15] considered how to find feasible solutions among a set of solutions in the presence of multiple stochastic constraints; Andradóttir and Kim [23] considered how to select the best feasible solution when there is a stochastic constraint.

CONCLUDING REMARKS

1. In this article, we consider the selection of the solution with the best mean

and the output of the computer experiments at the solution is modeled as a normal random variable. There are also other types of selection problems. For instance, Bernoulli selection problem selects the solution with the highest probability of success [24], multinomial selection problem selects the solution that is most likely to be the best [25], and comparison-with-a-standard problem selects the best solution only if it is clearly better than the standard [26,27].

2. The formulations and procedures introduced in this article are all frequentist's procedures. There are also Bayesian formulations of R&S problems; for example, the optimal computing budget allocation of Chen *et al.* [28] and the Bayesian procedures of Chick and Inoue [29,30]. They solve the problem of allocating a fixed number of samples to maximize the posterior probability of correct selection. Branke *et al.* [31] compared different procedures, frequentist's and Bayesian, through comprehensive numerical study. They concluded that Bayesian procedures are typically less conservative, and thus more efficient.
3. Selection of the best is related to another statistical problem known as *multiple comparisons*, which compares the means of all k solutions [1]. For instance, the problem of all pairwise comparisons aims to provide a joint confidence interval for $\mu_i - \mu_j$ for all $i \neq j$. The Tukey–Kramer test ([32]) and the Bonferroni approach ([33]) are often used to solve the problem.
4. R&S procedures have been implemented by some commercial simulation and optimization software packages. For instance, the Process Analyzer of Arena® simulation software implements the subset selection procedure of Nelson *et al.* [19] to compare different scenarios; the simulation optimization software OptQuest® implements the IZ selection procedure of Pichitlamken *et al.* [20] to conduct a “cleanup”, that is selecting the best among all visited

solutions after the optimization process finishes; and the Scenario Selector of AweSim® simulation software implements a number of R&S procedures including both, subset selection procedures and IZ selection procedures to compare different scenarios [34].

Acknowledgments

The author would like to thank Barry L. Nelson for teaching him R&S and for years of collaboration on R&S. The research is supported in part by the Hong Kong Research Grants Council under the grants GRF 613706 and GRF 613907.

STATISTICAL PROCESS CONTROL

FLAVIO SANSON FOGLIATTO

MICHEL J. ANZANELLO

Department of Industrial Engineering,
Federal University of Rio Grande
do Sul, Porto Alegre, Brazil

Statistical quality control (SQC) was conceived at Bell Telephone Laboratories by Walter A. Shewart in the 1920s. Shewart proposed the use of control charts (CCs) as the primary tool in SQC. The idea was to provide constant monitoring of processes through sampling units of production and measuring important quality characteristics (QCs). Since the seminal proposition of CCs for variables, many other charts have been presented in the literature; for example, cumulative sum, exponentially weighted moving average, and multivariate charts. Although varying in terms of construction, these CCs aim at a common objective: to monitor process variation and, in the case of multivariate charts, covariation. In SQC, quality is viewed as being inversely proportional to variability.

Process variation due to different sources is transferred to QCs and detected in their output readings. Two variation sources are important in SQC; they are named *common* and *assignable*. Common sources of variation are inherent to processes, and should not compromise the quality of their outputs. Processes exposed solely to common causes of variation are deemed as being in a state of statistical control (or in-control). On the other hand, processes exposed to assignable sources of variation are said to be out of statistical control (or out-of-control). Such sources are incidental and may be related to operator errors, variation in raw material specifications, or equipment malfunctioning, among others. CCs are useful in detecting assignable sources of variation, indicating a process change in status, from in-control to out-of-control.

CCs vary according to the QC under monitoring and how they are inputted in the chart. QCs represented by continuous measurements, such as moisture content in a food product or diameter of an auto part, are plotted in variables CCs. QCs measured as counts, such as the number of defective parts in a production lot, are plotted in attributes CCs. Data informed in a CC for variables may be inputted as individual measurements, means calculated from a group of measurements or an accumulative sum of measurements, leading to different types of CCs. In all the cases, interpretation of the information inputted in the chart is similar, as explained next.

A typical CC is given in Fig. 1. The process under surveillance is sampled at predetermined time intervals, and a measurement of interest (such as the sample average in this example) is plotted in the chart. Samples points are connected through lines to help visualizing process behavior. The CC is bounded by two lines: UCL = upper control limit and LCL = lower control limit. These limits are determined such that samples taken from a process that is in-control are expected to yield measurements predominantly within its boundaries. A center line (CL) is also displayed in the chart, giving the expected measurement value in case no assignable causes are present in the process. In-control processes are characterized by sample measurements predominantly within the control limits, randomly distributed above and below the CL. Deviations from this behavior indicate the presence of assignable causes of variation, leading to an out-of-control state. A number of rules may help in detecting an out-of-control situation in a CC. For example, when 3σ control limits are used (i.e., limits positioned at a 3σ distance from the CL, where σ is the process standard deviation), 1σ and 2σ limits may be added to the chart and the following rules applied to detect an out-of-control state: (i) two out of three consecutive points positioned

Figure 1. Representation of a typical control chart.

beyond the $\pm 2\sigma$ limits; (ii) four out of five consecutive points positioned beyond the $\pm 1\sigma$ limits; and (iii) eight consecutive points positioned in the same side of the CL.

Adequate process sampling is the key in SQC. Samples typically comprise a number of measurements gathered in subgroups from which statistics are calculated and inputted in the CC. In general, subgroup sizes should be kept small such that every sample is homogenous. The objective is to minimize the chance that when a change occurs in the process, it occurs between sampling times and not within the extraction of one sample. Three to eight data points are typical in the case of variable data; for attributes, larger samples sizes are recommended. Data points may be continuously sampled from the process and consolidated in subgroups at fixed time intervals, or collected only near the time the sampling is done. Frequent sampling of small subgroups from the process tends to give better results if compared to taking few large samples.

Another key issue in SQC is the CC design. Data inputted in a chart are assumed to follow a known probability distribution, usually the Normal. Therefore, the choice of control limits results in a probability that data points will fall within its boundaries. Consequently, there may be points that, although plotted beyond the control limits, were sampled from an in-control process. This is called a *false alarm*. The opposite may also happen, that is, samples from an out-of-control process positioned within the control limits. This is called a *failure to detect*. In well-designed CCs, the

probability of these two errors should be kept as small as possible. A quantity called the *average run length* (ARL) links these two probabilities; it represents the average number of points within control limits in a chart before a point falls beyond limits. Ideally, ARL should be maximized when the process is in-control, and minimized when the process is out-of-control. In Shewart-type charts, if p is the probability of a point plotting beyond control limits, $ARL = 1/p$, since p is constant over all samples. Finally, setting the parameters in a CC requires sampling from a process that is known to be in-control. CC design and process parameter estimation are part of what is referred to as the *Phase 1* of a CC implementation; Phase 2 takes place when the CC starts to be used for process monitoring.

Process capability is a concept related to SQC. To be considered capable, a process must produce units conforming to specifications. If specification limits on a QC are tighter than the control limits set for the same QC in a CC, then the process is likely to be considered as being not capable (in cases where the statistic plotted in the CC corresponds to the QC, e.g., when process is monitored through individuals charts, then the process will be considered as being not capable). Although out-of-control processes may still yield conforming products, such situation is not desirable since such processes are unpredictable regarding their outputs. Capability is determined through indices that basically measure a scaled distance

between control and specification limits; for example, C_p and C_{pk} .

In sections that follow, we describe the fundamentals of CC for variables and attributes, as well as modifications on traditional CCs. The chapter is concluded by a brief explanation on process capability indices.

CONTROL CHART FOR VARIABLES

Several QCs used for process control can be expressed by numerical measurements, named *variables* (e.g., dimension, volume, and weight, among others). CCs for variables aim at monitoring process location and variability. The location is monitored using an $\bar{X}$ chart (see Fig. 1), while variability can be accounted by the range CC, R , or by the standard deviation CC, S . It is important to monitor both mean and variability charts in process control procedures. A process may be centered (i.e., in control regarding the mean chart) and yet present excessive variability, which may compromise its capability; the opposite may also take place. The methods for process control described here assume that the measurements follow an approximately normal distribution.

Phase 1 of process control starts constructing the CCs. The $\bar{X}$ chart depicts the process mean by plotting the averages of samples of size n collected from sample intervals of size h . The control limits and the center line of the chart are functions of the parameters $\mu_{\bar{X}}$, which gives an estimate of the process mean μ , and $\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}}$, which gives an estimate of the process standard deviation σ . These parameters are usually unknown and must be estimated from process observations. Samples consisting of 20 to 25 observations are recommended, and must be collected from in-control processes [1,2].

The average of observations x_i is calculated as in Equation (1), while an estimator of $\mu_{\bar{X}}$ is given in Equation (2):

$$\bar{x} = \sum_{i=1}^n x_i / n \quad (1)$$

$$\bar{\bar{x}} = \frac{\sum_{i=1}^k \bar{x}_i}{k}, \quad (2)$$

with k as the number of samples.

An estimator of $\sigma_{\bar{X}}$ is a function of sample size and sample range, as in Equation (3). The range measure is widely used due to its simplicity and high efficiency, especially with small samples (i.e., $n = 4$ or 5).

$$\hat{\sigma}_{\bar{X}} = \frac{\bar{R}}{d_2 \sqrt{n}}. \quad (3)$$

In Equation (3), d_2 is the average relative range, defined as the relation between the range and the standard deviation of a normally distributed variable (i.e., $W = R/\sigma$), and $\bar{R}$ is the average range from the k samples. d_2 values are found in statistical tables and depend on n [1,3].

The control limits for the process mean are represented by

$$UCL = \bar{\bar{x}} + \frac{3}{d_2 \sqrt{n}} \bar{R} = \bar{\bar{x}} + A_2 \bar{R} \quad (4)$$

$$CL = \bar{\bar{x}} \quad (5)$$

$$LCL = \bar{\bar{x}} - \frac{3}{d_2 \sqrt{n}} \bar{R} = \bar{\bar{x}} - A_2 \bar{R}, \quad (6)$$

where A_2 is available in statistical tables and depends on sample size [1,4]. The limits calculated using Equations (4) and (6) are commonly referred to as 3-sigma limits.

The R CC, aimed at monitoring the range of samples consisting of n observations, is obtained in a similar manner. We first estimate μ_R e σ_R as

$$\hat{\mu}_R = \bar{R} \quad (7)$$

and

$$\hat{\sigma}_R = d_3 \frac{\bar{R}}{d_2}, \quad (8)$$

with d_3 as the standard deviation of W . The control limits for the R chart are

$$\text{UCL} = \bar{R} + 3d_3 \frac{\bar{R}}{d_2} = D_4 \bar{R} \quad (9)$$

$$\text{CL} = \bar{R} \quad (10)$$

$$\text{LCL} = \bar{R} - 3d_3 \frac{\bar{R}}{d_2} = D_3 \bar{R}. \quad (11)$$

Similar to previous cases, D_3 and D_4 can be found in statistical tables [4].

Phase 2 of process control consists of collecting further samples of size n (i.e., new observations of a running process), estimating the statistics $\bar{x}$ and $\bar{R}$, and plotting the statistics on the CC. As long as $\bar{x}$ and $\bar{R}$ remain within limits and chart points are randomly distributed along the CC, the process is considered to be in statistical control. Consider the data in Fig. 1 as observations collected in Phase 2; there are clearly two points violating the UCL, denoting that the process is out-of-control.

Montgomery [1] states that the $\bar{X}$ chart is efficient in detecting large variations on the process, for example, variations in the interval from 1.5σ to 2σ . The detection of smaller variations, however, requires other CCs such as the *CUSUM* (Cumulative Sum Control Chart) and *EWMA* (exponentially weighted moving average) charts.

The *CUSUM* chart relies on the cumulative sum of deviations between the sample values and the target value, incorporating all the information in the sample sequence [see Equation (12)].

$$C_i = \sum_{j=1}^i (\bar{x}_j - \mu_0), \quad (12)$$

with C_i as the cumulative sum until sample i , $\bar{x}_j$ as the average of the i th sample, and μ_0 as the process average target. In the absence of variation in the process, C_i is randomly distributed around zero. In case the process average moves from μ_0 to μ_1 ($\mu_1 \neq \mu_0$), there is an increasing trend if $\mu_1 > \mu_0$, and a decreasing trend if $\mu_1 < \mu_0$. In addition, the *CUSUM* chart is highly recommended for monitoring the process relying on a single observation ($n = 1$).

A second alternative for detecting small variations on the chart mean is the *EWMA*. Similar to the *CUSUM* chart, the *EWMA* chart can handle single observation data ($n = 1$). The z_i statistic for the *EWMA* chart is given as [1]

$$z_i = \lambda x_i + (1 - \lambda)z_{i-1}, \quad (13)$$

with $0 < \lambda \leq 1$ as the weighting factor of observation x_i . The metric z_0 , which is associated to observation x_1 , can be the process target or the average of previous observations (i.e., $z_0 = \bar{x}$). The *EWMA* chart gives more weight to samples recently collected from the process [see Equation (13)]. This enables fast detection of process changes, but turns the chart vulnerable to false alarms.

An important assumption underlying above charts is the consideration that observations are normally distributed. However, observations departing slightly from the normality can also be monitored by these charts due to the central limit theorem.

CONTROL CHART FOR ATTRIBUTES

Several QCs cannot be properly represented by numerical measurements. In this case, each item can be classified as conforming or nonconforming to a specification of interest. This type of QC is named *attribute*. For example, consider a manufacturing process that produces glass jars: a jar that does not present one or more required QCs (e.g., size) is classified to be nonconforming. There are three basic CCs for attributes in literature: (i) CC for fraction of nonconforming (p chart), (ii) CC for number of nonconformities (c chart), and (iii) CC for the number of nonconformities per unit (u chart). Due to space restrictions, we explain the first of these charts.

The fraction, or percentage, of nonconforming arises as a simple and efficient measurement unit in process control. Although beyond the scope of this article, it is easy to prove that the statistical principles underlying the fraction of nonconforming CCs are based on the binomial distribution [1]. Consider p as the probability of having a nonconforming unit; if p is known, one can use

the binomial distribution to construct the p CC. This is not the usual situation, so $\hat{p}$ (i.e., the estimator of the nonconforming fraction) needs to be estimated from the population as in Equation (14).

$$\hat{p}_i = \frac{D_i}{n} \quad i = 1, 2, \dots, k, \quad (14)$$

with D_i as the number of nonconformities in sample i , and n as the number of items in that sample. It is usual to collect k samples. The average of the nonconforming fraction comes as

$$\bar{p} = \frac{\sum_{i=1}^k \hat{p}_i}{k}. \quad (15)$$

The control limits for the p chart are given by

$$UCL = \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} \quad (16)$$

$$CL = \bar{p} \quad (17)$$

$$LCL = \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}. \quad (18)$$

Phase 2 of the process control procedure is performed as previously done in CCs for variables: collect further samples of size n , estimate the statistic $\hat{p}$, and plot $\hat{p}$ on the CC. As long as $\hat{p}$ remains within control limits and randomly distributed along the CL, the process is considered to be in-control. Points that exceed the boundaries should be investigated regarding assignable causes [1,2].

OPTIMIZING PROCESS SAMPLING: ADAPTIVE CHARTS

Several modifications in the classic Shewhart CCs have been proposed in the literature. They aim at providing better tools for monitoring processes; one such modification is the adaptive CC. Charts are said to be adaptive when one or more of their parameters (sample size, sampling frequency, and control limit coefficient) are allowed to vary during process monitoring.

Adaptive CCs work as follows. Consider a chart with sample points plotted in the region between warning limits (usually set at $\mu \pm 2\sigma$) and control limits given by $\mu \pm L\sigma$, where L (> 2) is user defined and usually equal to 3. Let that region be called the *warning region*. Since points are in that region, it is possible that the process has shifted to an out-of-control state. To verify that the next sample should be taken sooner or be larger; alternatively a smaller value of L could also be adopted. On the other hand, if sample points are plotted near the center line, chart parameters may be relaxed. When the process is in-control, such policy should lead to a reduction in the mean time to signalize a special cause, and in the average inspection cost.

In theory, the area between control limits could be divided into multiple warning regions, each with different chart parameter settings. Thus, every time a sample point falls into one of these regions, one of several combinations of values for n (sample size), h (sample interval), and L (control limit coefficient) would be chosen according to the most recent information. However, works by Reynolds *et al.* [5], Reynolds and Arnold [6], Runger and Pignatiello [7], and Reynolds [8] have demonstrated that using only two values for n , h , and L leads to better results in terms of minimizing the mean time to signal a special cause.

To compare the performance of alternative adaptive CCs, Reynolds *et al.* [5] proposed two indices: (i) ANSS—average number of samples to signal, defined as the expected number of samples taken from the process until an out-of-control state is signalized; and (ii) ATS—average time to signal, corresponding to the expected time until the chart signalizes an out-of-control state. Under fixed control limits, the probability q of a sample point beyond control limits is independent of the sampling interval, be it fixed or variable. Thus, if no changes take place in the process, the random variable N representing the number of samples to signal is described by a geometric distribution with parameter q . The ANSS is then defined as $ANSS = E(N) = 1/q$. If the process state remains unchanged, the sampling intervals

$h_1, h_2, \dots$ are independent and identically distributed and the ATS is given by $ATS = E(N)E(h_i) = ANSS \times E(h_i)$. In addition to ATS and ANSS, other performance indices have been proposed to the adaptive charts; for example, ANOS—average number of observations to signal [9,10] to analyze CCs where n is variable; and ANSW—average number of switches [11] to analyze charts with adaptive sampling interval.

In addition to the statistical indices described above, determination of the best set of values for the chart parameters may also be based on economic issues. The following economic performance indices have been adopted in works on adaptive charts by authors such as Das *et al.* [12] and Prabhu *et al.* [13]: ETC—expected total cost, giving the process control costs for a production of known and finite size, and ECTU—expected cost per time unit. ECTU is suitable for processes that operate continuously; in case of small lot productions, both indices lead to similar results.

We now give details on the $\bar{X}$ CC with adaptive sampling interval. Our presentation is mainly based on Reynolds *et al.* [5], Runger and Montgomery [14], and Reynolds [15]. Other adaptive charting schemes are reviewed in Tsung and Wang [16].

The adaptive $\bar{X}$ chart works as follows. Assume a QC following a normal distribution with mean μ and known variance σ^2 , where μ_0 is the target mean value. The CC center line is given by μ_0 and the control limits are $\mu_0 \pm L\sigma/\sqrt{n}$. The area between control limits is divided in r regions $I_1, I_2, \dots, I_r$, each

corresponding to a sampling interval h . If the mean $\bar{x}_i$ of sample i is plotted in region I_j , then the next sample $i + 1$ is taken from the process after an interval h_j . The shortest sampling interval $h_{\min}$ is determined considering the minimum time needed to take a sample from the process; the longest interval $h_{\max}$ corresponds to the maximum reasonable time interval for which the process runs unobserved. Although possible, the use of r different intervals in cases where the process mean is $\mu \neq \mu_0$ leads to a larger ATS value if compared to using only two sample intervals ($h_{\min}$ and $h_{\max}$), as demonstrated by Reynolds *et al.* [5], among others. These authors propose the following optimal sampling policy:

$$\begin{aligned} h_{\min} \text{ when } & \begin{cases} \mu_0 - L\frac{\sigma}{\sqrt{n}} \leq \bar{x} < \mu_0 - w\frac{\sigma}{\sqrt{n}} \\ \text{or} \\ \mu_0 + w\frac{\sigma}{\sqrt{n}} < \bar{x} \leq \mu_0 + L\frac{\sigma}{\sqrt{n}} \end{cases} \\ h_{\max} \text{ when } & \mu_0 - w\frac{\sigma}{\sqrt{n}} \leq \bar{x} \leq \mu_0 + w\frac{\sigma}{\sqrt{n}}, \end{aligned} \quad (19)$$

where w is the parameter that divides the area between control limits in a central region, and two warning regions close to the control limits, as depicted in Fig. 2.

The value of w may be determined to allow comparison between the performance of the adaptive and the fixed sampling interval CCs. For this, when $\mu = \mu_0$, both charts must present the same ANSS, ATS, and sampling rate. The same ANSS value is obtained using the same L when setting the control limits for the charts. The ATS value depends on the

Figure 2. Example of a control chart with adaptive sampling interval.

sampling interval and w . If the interval in the fixed chart is h_f , the adaptive intervals must satisfy the condition $E(h_i) = h_f$. If two sampling intervals h_s (short) and h_l (long) are used and the sample mean is normally distributed, then w is given by

$$w = \Phi^{-1} \left[\frac{2\Phi(L)(h_f - h_s) + h_l - h_f}{2(h_l - h_s)} \right], \quad (20)$$

where $\Phi(\cdot)$ is the standard normal distribution function and $h_s < h_f < h_l$. If $h_f = 1$ (i.e., one time interval), then $E(h_i) = 1$, and the expression (20) is rewritten as

$$w = \Phi^{-1} \left[\frac{2\Phi(L)(1 - h_s) + h_l - 1}{2(h_l - h_s)} \right]. \quad (21)$$

Pairing the two CCs as proposed above allows comparison of ATS values for different values of $\mu_1 \neq \mu_0$, searching for the chart that best detects the shift in μ . It is convenient to express shifts from μ_0 to μ_1 in terms of standard deviations, that is, consider $\mu_1 = \mu_0 + k\sigma$ and then calculate the values of ATS as a function of k .

PROCESS CAPABILITY: DEFINITION AND INDICES

Process capability may be broadly defined as the ability to meet customer demands regarding process outcomes. The basic idea is to compare the admissible process variation range, represented by the specification limits, with the actual process variation. Specification limits may be unilateral or bilateral, leading to different capability assessments in each case. In the case of bilateral limits, a process is deemed as capable whenever 99.73% of its outcomes are within specification limits; the value was chosen to correspond to an area under the normal curve bounded by $\mu \pm 3\sigma$. For unilateral limits, the threshold value is 99.865%. Process capability should only be assessed in processes that are in-control.

The process capability indices (PCIs) C_p , C_{pk} , C_{pm} , and C_{pmk} were originally conceived to be used in normally distributed data. All their statistical figures, such as point estimates and confidence intervals, rely on that

assumption. Although important, the normality assumption is not mandatory for process capability assessment, since PCIs have also been proposed for nonnormal data; see Montgomery [1].

PCIs may be divided into two categories according to the loss function in which they are founded: (i) those with behavior analogous to “goal posts” in a football game and (ii) those based on Taguchi’s loss function. Indices in (i) are C_p and C_{pk} ; they associate no loss to a QC with outputs within specification limits. Indices in (ii) are C_{pm} and C_{pmk} ; they penalize outputs proportionally to their deviation from the specification target value. In what follows, we detail indices in class (i).

In the calculation of C_p and C_{pk} variation within subgroups (σ_{ST}) is considered, the process generating the data is assumed to be in-control, and data points are independent and normally distributed. An estimate of σ_{ST} was needed to set the control limits of the CCs used to monitor process behavior; the above may be used in this calculation. In processes monitored through $\bar{X}$, and R charts, the estimate is $\hat{\sigma}_{ST} = \hat{\sigma}_{\bar{R}} = \frac{\sum_{i=1}^k R_i/k}{d_2}$, where k is the number of subgroups considered and d_2 is a tabled value, available in Duncan [4]. The expression for C_p is

$$C_p = \frac{USL - LSL}{6\hat{\sigma}_{ST}},$$

where USL and LSL are the upper and lower specification limits, respectively. C_p values in the interval [1.00, 1.33] denote processes with reasonable capacity; when $C_p \geq 2.0$ process capacity is deemed as excellent. Kotz and Johnson [17] recommend $C_p \geq 1.67$ in the case of new processes and $C_p \geq 1.50$ for existing processes. For processes with unilateral specifications, C_p is modified as follows:

$$C_{PU} = \frac{USL - \mu}{3\hat{\sigma}_{ST}} \quad \text{or} \quad C_{PL} = \frac{\mu - LSL}{3\hat{\sigma}_{ST}}.$$

Whenever the process target T (represented by μ) differs from the specification interval mean point M , C_p overestimates the process capability and C_{pk} should be used:

$$C_{pk} = \text{Min}(C_{PL}, C_{PU}).$$

While C_p takes only the process standard deviation into account, C_{pk} is a function of both the process average and standard deviation. The values of C_p and C_{pk} coincide whenever $T = M$. For more details on process capability indices, see Montgomery [1] and Kotz and Johnson [17].

STOCHASTIC DYNAMIC PROGRAMMING MODELS AND APPLICATIONS

MEHMET A. BEGEN

Ontario Canada

INTRODUCTION

Stochastic dynamic programming (DP) models are similar to deterministic DP models [1,2] in terms of states, stages, actions/decisions, and rewards (costs or payoffs) but differ in their state transitions.

In formulating DPs, determining the state correctly can be difficult but crucial for the solution. We can assume the state to be a description of the system that gives the information required to make conscious decisions. Actions are the decision alternatives that the decision maker can choose when the system is in a particular state and influence the future states. Stages are the epochs that a decision is made and there is a change in system's state. Rewards are the payoffs or the costs that the system incurs at each stage with a choice of action for a given state. State transition specifies (the distribution of) the next stage's state given a pair of action and state of the current stage. The functional equation is a link between the current stage's problem and the next stage's problem. Its solution gives an optimal action for each possible state at that stage.

In deterministic DP models, a specification of a state and action pair at the current stage determines the next stage's state with certainty, that is, there is no ambiguity in state transitions. Figure 1 is an example for a state transition of a deterministic DP model.

In stochastic DP models, the state in the next stage is not known deterministically in advance and can only be given probabilistically, that is, given a state and an action

pair, there is some probability that the system will be in some state in the next stage. One can represent this, for each action, in a matrix where rows and columns represent states and the entries of the matrix are probabilities. This matrix is called the *state transition probability matrix*. We can think of deterministic DP models as special cases of stochastic DP ones where the state transition probability matrix (of a state and action pair) consists of only 1 s and 0 s. This is also reflected in the functional equation of the stochastic DP. A generic functional equation for deterministic DP (of a maximization problem) can be given as $f_n(s) = \max_a \{r(s, a) + f_{n+1}(s')\}$ where s is the current state, a is the action taken while in state s , $r(s, a)$ is the expected reward obtained with the state and action pair (s, a) , s' is the state in stage $n + 1$, and finally $f_n(s)$ is the maximum expected reward that can be earned when the state is s in stage n . State s' is determined precisely by state s and action a . In stochastic DP models, we can revise this equation by redefining $r(s, a) = \sum_j \text{prob}(j|s, a) r(j|s, a)$ and $f_{n+1}(s') = \sum_j \text{prob}(j|s, a) f_{n+1}(j)$, where $\text{prob}(j|s, a)$ is the probability that the system will be in state j in the next stage given that the system is in state s and action a is chosen in the current stage, and $r(j|s, a)$ is the reward obtained in the next stage if the state is s and action a is taken in the current stage. Therefore, $r(s, a)$ and $f_{n+1}(s')$ now represent expected values. Furthermore, specifying an action a in state s does not suffice to determine the state in the next stage; the system can be in state j with probability $\text{prob}(j|s, a)$. Figure 2 shows the evolution of states in a stochastic DP model.

Rewards and state transition probabilities on stage n may be different than other stages and therefore one may need to use stage-dependent $r_n(s, a)$ and $\text{prob}_n(j|s, a)$. Throughout the article, we assume stationary rewards and state transition probabilities. Furthermore, we focus on finite-horizon models, that is, $1 \leq n \leq N < \infty$. In finite horizon problems,

Figure 1. State transition of a deterministic DP model.

Figure 2. State transition of a stochastic DP model.

one may solve both the deterministic and stochastic DPs with backward induction [1] by solving $f_N(s) = \max_a r(s, a)$ and then solving $f_n(s) = \max_a \{r(s, a) + f_{n+1}(s')\}$ for $n = N-1, N-2, \dots, 1$. At each stage, for each possible state, an optimal action is determined. (Backward induction is the only way of solution for finite-horizon stochastic dynamic programs.) By comparing the functional equations for deterministic and stochastic DPs, we see that the number of (arithmetic) operations for a stochastic problem is more than that for a deterministic one of a similar size.

Deterministic DP models have no standard formulation and are considered to be an art [1–4]. Stochastic DP models are not an exception and have more variety of formulations. DP models are best understood by examples. Before discussing a selection

of stochastic DP applications, we start with an application of deterministic DP resource allocation model and consider its stochastic version.

MODELS AND APPLICATIONS

Resource Allocation

Resource allocation problems can be seen in a variety of contexts. We start with a deterministic example and introduce stochastic aspects to the problem later. There are a number of alternatives (e.g., investments, projects) and a certain amount of resource (e.g., money, budget, labor) that needs to be allocated to each alternative to achieve a certain objective (e.g., maximize total payoff): to make things concrete, we consider N investments with a total available budget of S dollars. Let $r_n(a)$ be the return of investment n if amount a is allocated to it and $f_n(s)$ be the maximum expected reward that is earned with investments $n, n+1, \dots, N$ when there are s dollars available for the investments $n, n+1, \dots, N$.

We first consider the allocation problem where the investment decisions have to be made simultaneously and investments will commence at the same time. The functional equation for this problem can be written as $f_n(s) = \max_{a \leq s \leq S} \{r_n(a) + f_{n+1}(s-a)\}$ for $n = 1, 2, \dots, N-1$ and $f_N(s) = \max_{a \leq s \leq S} r_N(a)$ in which the state in the next stage is $(s-a)$ (amount left available for investments $n+1, n+2, \dots, N$) when the current state is s (s dollars are the available budget for investments $n, n+1, \dots, N$) and the decision maker takes action a (amount of money allocated to investment n). The functional equations for investment n state that an allocation is made such that the current investment return, $r_n(a)$, plus the best possible return of remaining investments, $f_{n+1}(s-a)$, is maximized. If there is only a single investment alternative left, that is, $n = N$, then the allocation is just chosen to maximize the return of investment N . One can solve this problem by backward induction.

Now suppose the return of investment n can be either $K_n(a)$ with probability p_n or $k_n(a)$ with probability $q_n = 1 - p_n$. We

consider two different extensions. In the first extension, the allocation decisions are to be made simultaneously and investments start at the same time (as above in the deterministic case). In the second extension, the decisions are to be made sequentially, that is, an investment is realized and its return is acquired before we invest the next one.

The first case is almost identical to the deterministic case. We only need to redefine $r_n(a)$ as $p_n K_n(a) + q_n k_n(a)$, that is, reward is now the expected return of investment n . Note that we can still determine the next stage's state $(s - a)$ with certainty for a given current state and action pair (s, a) . Thus, we can classify this as a deterministic DP. On the other hand, in the second extension, the state in the next stage can only be given probabilistically for a given action and state pair (s, a) ; it can be either $s - a + K_n(a)$ with probability p_n or $s - a + k_n(a)$ with probability q_n . Therefore, the second case is an example of a stochastic DP and its functional equation becomes $f_n(s) = \max_{a \leq s} \{p_n K_n(a) + q_n k_n(a) + p_n f_{n+1}(s - a + K_n(a)) + q_n f_{n+1}(s - a + k_n(a))\}$ for $n = 1, 2, \dots, N - 1$ and $f_N(s) = \max\{s, \max_{a \leq s} K_N(a)p_N + k_N(a)q_N\}$. Again we can solve these two extensions with backward induction.

We now discuss several more applications of stochastic DP models.

Secretary Selection (Accepting the Best Offer)

Suppose we are hiring for a secretary position. There are N potential candidates and we interview each candidate one at a time. We assume that N is fixed and known to the decision maker, and that there exists a ranking among the candidates. After each interview, we can either choose to hire the person or continue by interviewing the next candidate in line. If we do not hire the current person we interview, they will go and find work elsewhere. Thus, they can be no longer hired. Ideally, we would like to hire the best candidate out of N people. However, we do not know the rank of the candidates, and we can only rank candidates that we have seen so far, for example, we can decide whether the current candidate is better than

any of the previous candidates that we have interviewed so far. Note that if the current candidate is not the best so far then the probability that this person is the best among all N candidates is zero, and if there are any people left to interview then there is still a possibility that the best candidate is yet to come. On the other hand, if the current interviewee is the best candidate seen so far, then we may choose to hire that person. We seek a decision rule that will maximize the probability of hiring the best candidate.

We start with determining the probability that the current candidate n is the best of N candidates if this person n is the best so far. We can think of this as conditional probability:

$$\begin{aligned} &\text{Prob}\{\text{the current candidate is the best of } N | \\ &\quad \text{the current candidate is best of } n\} \\ &= 1/N \div 1/n = n/N. \end{aligned}$$

To make a decision, all we need to know is whether the current candidate is the best so far or not. Therefore, we define the states as $\{B, NB\}$. (B means that the current candidate is the best seen so far and NB denotes the candidate is not the best.) We have only two decisions; hire or do not hire. If we choose to hire the current candidate n , the reward is the probability that person is the best of N , that is, n/N . On the other hand, if we do not hire the current candidate n , then we do not receive any immediate reward and interview the candidate $n + 1$. In this case, the probability that the next candidate will be the best seen so far is $1/(n + 1)$. Now we can write the functional equation for this problem. Let $f_n(s)$ be the maximal probability of selecting the best candidate after interviewing the candidate n and when the state is s (B or NB). Then $f_N(B) = 1$ and $f_N(NB) = 0$ and for $n = 1, \dots, N - 1$

$$\begin{aligned} f_n(NB) &= n/(n+1)f_{n+1}(NB) + 1/(n+1)f_{n+1}(B) \\ f_n(B) &= \max\{f_n(NB), n/N\}. \end{aligned}$$

In $f_n(NB)$, we do not have a choice but to interview the next candidate $(n + 1)$ since the current candidate n is not the best one

so far (and therefore not the best of N). In this case, with probability $n/n + 1$, the candidate $(n + 1)$ will not be the best (among the first $n + 1$ candidates) and with probability $1/n + 1$, the candidate $n + 1$ will be the best (among the first $n + 1$ candidates). On the other hand, in $f_n(B)$, we do have a choice since the current candidate is the best seen so far (and therefore there is a chance of n/N that the candidate is the best of N); we hire if the $n/N \geq n/(n + 1)f_{n+1}(NB) + 1/(n + 1)f_{n+1}(B)$, and do not hire otherwise.

The optimal policy is of the form—interview the first m candidates, and then hire the first candidate that is the best seen so far [3]. We can see this from the functional equation of the model: n/N is increasing in n and $f_n(NB)$ is decreasing in n , therefore there will be a value m after which n/N will be larger than $f_n(NB)$ and we will hire the first best candidate after seeing m candidates. (To see why $f_n(NB)$ is decreasing consider the following: the probability of selecting the best candidate when we rejected the first n candidates is at least as good as probability of selecting the best candidate when we rejected the first $n + 1$ candidates, therefore $f_n(NB)$ is decreasing in n .) As the number of candidates N increases, both the optimal proportion of candidates to interview before hiring m/N and probability of selecting the best candidate $f_1(\cdot)$ is reaching $1/e$ (or 36.8%). Hence, for large N , the optimal thing to do is to interview the first (approximately) 37% candidates and then hire the first candidate who has been the best so far.

This problem can also be thought of as accepting the best offer where a decision maker is presented with N offers in a sequential order [4]. After seeing an offer, the decision maker has to either accept or reject the offer. If an offer is rejected, then it is lost, and the decision maker knows only the relative rank of those offered. The objective is again to maximize the likelihood of choosing the best offer among N possible ones.

The secretary selection problem (or accepting the best offer) is a type of optimal stopping problem. The following is another example for the optimal stopping problem.

Selling an Asset

Suppose we are a real estate agent trying to sell a house. At the beginning of each week, if the house is still on the market, we must advertise it for another week. Advertising costs C dollars per week. Offers for the house will come in from buyers during the week, and at the end of week we must choose to either sell the house to the highest bidder or keep it on the market. If we do not sell the house, then we need to advertise it again next week. The bids received during the week will expire at the end of week and we receive new bids every week. The probability of receiving a bid b is $\text{prob}(b)$ and we can receive at most $m + 1$ different bids including a zero bid (i.e., receiving no bids in the week). If we sell the house then we will receive $r\%$ of the bid as commission; however, if the house is not sold after N weeks, then we will receive nothing (even though we have paid all the advertisement costs).

If the house is already sold, then there is no decision to make, and if it is still on the market then we need to know the maximum bid to decide whether to accept it (and sell the house) or not to sell it. Therefore, the state is given by the highest bid, and state space is $\{b_0, b_1, b_2, \dots, b_m, \text{sold}\}$. We assume $b_0 = 0$ and $b_i > 0$ for $m + 1 > i > 0$. We only have two actions: *sell* or *do not sell*. If the house is already sold then there is no decision to be made. Otherwise, we can choose *sell* or *do not sell*. If we sell, then we receive a commission of $r\%$, the process ends, and the system state becomes *sold*. If we do not sell (and the house is still in the market), then we pay C dollars (except in the week of N) and the system state will be determined by arrival of bids in the next week, that is, with $\text{prob}(b)$ s. Let $f_n(s)$ be the maximal expected value (of [commission - advertisement costs]) obtained after receiving the highest bid of s in week n . Then for all $s \neq \text{sold}$, we can represent the functional equations as

$$\begin{aligned} f_N(s) &= \max\{sr/100, 0\} \\ f_n(s) &= \max\{sr/100, -C + \sum_m \text{prob}(b_m) \\ &\quad \times f_{n+1}(b_m)\} \text{ for } n = 1, 2, \dots, N - 1. \end{aligned}$$

We can solve these equations by backward induction and determine an optimal action for each state in each week. In this problem, there is a threshold bid $L(n)$ for every week n . If $L(n)$ is larger than the highest bid, then we do not sell the house, and we sell it otherwise. This $L(n)$ number decreases as n gets larger (i.e., as it gets closer to week N) since there will be less number of weeks to sell the house.

Consider the following numerical example: $r = 15\%$, $N = 3$, $C = \$1000$, $b_0 = 0$ and $b_1 = \$150,000$, $b_2 = \$250,000$, $\text{prob}(0) = 0.3$, $\text{prob}(150,000) = 0.4$, $\text{prob}(250,000) = 0.3$. Then, $f_3(0) = 0$, $f_3(150,000) = 22,500$, $f_3(250,000) = \max\{0, 150,000 \times 15/100\}$, $f_3(250,000) = 37,500$, $f_2(0) = 19,250 = \max\{0.3 \times f_3(0) + 0.4 \times f_3(150,000) + 0.3 \times f_3(250,000), 0\}$, $f_2(150,000) = 22,500 = \max\{19,250, 150,000 \times 15/100\}$, $f_2(250,000) = 37,500$, $f_1(0) = 25,025$, $f_1(150,000) = \max\{25,025, 150,000 \times 15/100\}$, $f_1(250,000) = 37,500$. With these calculations and by keeping track of optimal action at this week (i.e., sell or do not sell), we can identify the optimal policy as follows: sell in Week 1 if the highest bid is $\$250,000$ and sell in Weeks 2 and 3 if the highest bid is at least $\$150,000$, that is, $L(1) = \$250,000$ and $L(2) = L(3) = \$150,000$. For more on this problem and its variants see Puterman [3] and Ross [4].

A Betting Game

Consider a game in which a player can bet any nonnegative amount up to her current wealth at each round of the game [4]. After the bet is placed, she will either win the bet amount with probability p or lose this amount with probability $q = 1 - p$. The game will be played N times, that is, she will bet N times. We assume the player is risk averse and her objective is to maximize her expected utility given by the $\log$ of her wealth at the end of the game, that is, after N bets. Then the question is how the bets should be placed.

We first have to determine the state, that is, the information needed to decide a bet amount. Obviously, she needs to know how much wealth she has before she places any bets. Suppose she has a current wealth of s and bet an amount of as ($0 \leq a \leq 1$), that is, a is the ratio of the bet to her current wealth s . Then, with probability p , her wealth level will

be $(s + as)$ and with probability $q = 1 - p$, the wealth level will be $(s - as)$. If there was only a single bet, $N = 1$, then the expected payoff would be $p \log(s + as) + q \log(s - as)$ and she would choose a such that this expected value would be maximized. Now, we extend this idea to $N > 1$. Let $f_n(s)$ be the maximal expected value of the objective if the current wealth is s and there are n more bets left. (The final stage, no more bets, is numbered as 0 in this formulation.) We have already defined the action as the ratio of the bet to the current wealth. Then, we can represent the functional equation for this stochastic DP model as

$$\begin{aligned} f_0(s) &= \log s \\ f_n(s) &= \max_{(0 \leq a \leq 1)} \{pf_{n-1}(s + as) + qf_{n-1}(s - as)\} \\ &\text{for } n = 1, 2, \dots, N. \end{aligned}$$

We solve these equations by using backward induction. We start with $n = 1$ (i.e., there is only one more bet remaining): $f_1(s) = \max_{(0 \leq a \leq 1)} \{p \log(s + as) + q \log(s - as)\}$. If $p \leq q$ (i.e., $p \leq 1/2$), then the optimal action is to bet nothing, that is, $a^* = 0$. (Rewrite the terms as $p \log(s + as) + q \log(s - as) + p \log(s - as) - p \log(s - as)$ and organize them as $p \log(s^2(1 - a^2)) + (q - p) \log(s(1 - a))$, both terms are maximized if $a^* = 0$.) This holds not only for $n = 1$ but also for all n . Suppose $p > q$ (i.e., $p > 1/2$), then we can determine $f_1(s)$ with calculus and obtain $a^* = p - q$. Therefore, $f_1(s) = p \log(s(1 + p - q)) + q \log(s(1 - p + q)) = p \log(2ps) + q \log(2qs) = K + \log s$, where $K = \log 2 + p \log p + q \log q$. Next, we find $f_2(s) = \max_{(0 \leq a \leq 1)} \{p \log(s + as) + q \log(s - as)\} + K$. We note that $f_2(s) = f_1(s) + K$ hence $f_2(s) = 2K + \log s$. Similarly, we see that $f_n(s) = nK + \log s$. Therefore, the optimal strategy for all rounds of the game is to bet a^*s , that is, $a^* = (p - q)s$ when $p > q$.

Hunting Preference of a Lion

We consider the hunting decisions of a lion 3. The objective of the lion is to maximize the probability of its survival over the next 20 days. Each day the lion can choose whether to hunt or not to hunt. We assume (for simplicity) that the lion considers only one type

of prey. Besides hunting on its own, the lion can also choose to hunt in a group of lions up to eight. The hunt success chance increases with the number of lions in the group. The hunt success probability is estimated by $p(k) = 0.04 + 0.05k$, where k ($1 \leq k \leq 8$) is the number of lions in the group. If a hunt is successful, the lions share their prey equally. Furthermore, lions do not make more than one hunt attempt per day.

The lion needs approximately 6 kg of meat a day and has a gut capacity of about 30 kg. Hunting requires an additional 0.5 kg of food energy and this number does not change with the number of lions involved in a hunt. If the energy reserve of the lion reaches zero, it dies. On the other hand, preys have average edible meat of 247 kg, and so can satisfy the food demand of several lions.

We will build a stochastic DP model for this problem. Stages are naturally given as days; we add a day to determine the survival probability at the end of 20 days. The actions are whether to hunt or not, and if to hunt, in what size group. We may represent the actions as $\{0, 1, \dots, 8\}$ where 0 represents no hunt (NH). However, in this problem, we may consider only actions: hunt with a group of 8 or NH. This is because as the group size k increases, the success rate of a hunt increases (given by $p(k)$), the food consumption for a hunt does not change (it is 0.5 kg of food energy for any k , and in fact we would expect the lion to consume less as k increases), and a hunt with a group of eight results in more than $(247/8 > 30)$ 30 kg of meat for each lion. Therefore, with these numbers, lions will always choose to hunt in a group of eight (if it chooses to hunt) and we represent the actions as H (hunt with a group of eight) and NH. Next, we need to think about the state for the problem. What is the information that the lion requires to decide whether to hunt or not? It is the amount of food energy level at the beginning of a day; since the total capacity is 30 kg and a hunt consumes 0.5 kg, we can represent the state space as $\{0, 0.5, 1, 1.5, \dots, 30\}$, where 0 denotes the death state. If the lion has an energy level of s and chooses to hunt, then its energy level the next day will be 30 with probability $p(8)$ and be $\max(0,$

$s - 6.5)$ with probability $1 - p(8)$. If the lion does not hunt, then its energy level the next day will be $\max(0, s - 6)$. Furthermore, $\text{prob}\{0 | 0, \cdot\} = 1$. We are now ready to write down the functional equations for this problem. Let $f_n(s)$ be the probability of survival (at the end of 20 days) if there are n days to go and the lion's energy reserve is s . Then

$$\begin{aligned} f_n(0) &= 0 \text{ for } n = 0, 1, 2, \dots, 20 \\ f_n(s) &= \max\{f_{n-1}(\max\{0, s - 6\}), p(8)f_{n-1}(30) \\ &\quad + (1 - p(8))f_{n-1}(\max\{0, s - 6.5\})\} \\ &\text{for } n = 1, 2, \dots, 20 \text{ and} \\ &\quad s = 0, 0.5, 1, 1.5, \dots, 30. \end{aligned}$$

We can solve this problem by backward induction and determine $f_{20}(s)$, probability of the lion's survival after 20 days if its current energy level is s . By tracking down the optimal action (NH or H) for each day, we can determine the lion's optimal decisions daily over the horizon of 20 days. For instance, if the lion's energy level is 6.5, then its survival probability at the end of 20 days is about 30% and if the energy level is 7 the survival probability jumps to 46%. With an energy level of 6.5 at the beginning of Day 1, the lion chooses not to hunt on Day 1 but hunts on Day 2; and with an energy level of 7 (or more), the lion chooses to hunt on Day 1.

Hockey Goalie or No Goalie

In ice hockey, there are usually (e.g., no power play) five players and one goalie playing for each team. The goalie is the most important defense player. However, if toward the end of the game the team is losing, the coach of the losing team may decide to pull his goalie, that is, replace the goalie with another player. This decision gives the pulling team a 6-to-5 skater advantage over the opposing team and increases the pulling team's chance to score. However, at the same, it increases the likelihood of the opponent to score as well and at a larger factor. However, the pulling team may score and tie the game with this decision. (In the 2010 Winter Olympic Games in Vancouver, we have seen examples of this

strategy.) Then the question is to determine when (if ever) should a team pull the goalie? This problem is studied in literature [5,6] and our example is from Puterman [3].

We build a stochastic DP model for a hockey coach whose team is losing near the end of the game. The coach estimates the following: pulling the goalie will increase the probability that the coach's team scores the only goal in the next t seconds from p_G to p_{NG} ; however, the probability that the opponent team scores the only goal in this t -second time interval rises from q_G to q_{NG} . The coach assumes that the events in successive t -second intervals are independent. The coach's objective is to maximize the probability of having at least a tie.

The most difficult part of this problem is to determine a state variable. One good choice is the score difference between the teams; the score of the coach's team - the score of the opposing team, $\{\dots, -2, -1, 0, 1, 2, \dots\}$. Given such a state definition, it is obvious that, if the score difference were zero or greater, then the coach would not pull the goalie. Stages are every t -second intervals. Suppose there are Nt seconds left in the game (then we can simply assume $N + 1$ stages and work with $n = 0, 1, 2, \dots, N$). The coach has two actions: let the goalie play (G) or pull the goalie (NG). Let s be the current state, then state transitions are as follows: suppose the coach chooses action G , then with probability p_G the coach's team will score in the next t seconds so the new state will be $s + 1$, with probability q_G , the opposing team will therefore score and the new state will be $s - 1$, and with remaining probability $1 - p_G - q_G$, there will be no scoring so it will be s . The same structure holds for the action of NG except the probabilities change. Thus we have: $\text{prob}(s + 1|s, G) = p_G$, $\text{prob}(s|s, G) = 1 - p_G - q_G$, $\text{prob}(s - 1|s, G) = q_G$, and $\text{prob}(s + 1|s, NG) = p_{NG}$, $\text{prob}(s|s, NG) = 1 - p_{NG} - q_{NG}$, $\text{prob}(s - 1|s, NG) = q_{NG}$.

Now we write down the functional equations. Let $f_n(s)$ be the probability of having at least a tie after Nt seconds when the current score difference is s and there

are n more t -seconds to go. Then

$$\begin{aligned} f_0(s) &= 1 \text{ if } s \geq 0 \text{ and } f_0(s) = 0 \text{ if } s < 0 \\ f_n(s) &= \max\{R(G), R(NG)\} \text{ for } n = 1, 2, \dots, N \\ &\text{and } s = \dots, -2, -1, 0, 1, 2, \dots, \\ &\text{where } R(X) = p_X f_{n-1}(s + 1) \\ &\quad + q_X f_{n-1}(s - 1) + (1 - p_X - q_X) f_{n-1}(s) \\ &\text{for } X = R, NG. \end{aligned}$$

This model can once again be solved by backward induction and we can determine an optimal decision for each t -second interval by starting from $f_0(s)$ to $f_N(s)$ for all s .

OTHER APPLICATIONS

In this section, we briefly mention and list a few more applications of stochastic DP from literature. In Goto *et al.* [7], a stochastic DP model is developed to determine the number of (airline) meals to load on an airplane on various time intervals before its departure. The meals have to be prepared in advance; however, the exact number of passengers changes until the last minute. Authors show that the use of the model can improve customer service (by decreasing meal shortages) and save money. Another application [8] is from electrical engineering in which researchers use stochastic DP modeling to optimize streaming of media packetized over a lossy packet network (such as Internet). The trade-off is between the number of transmissions (cost) and probability of a packet being lost or delayed (quality). The model takes the current status of the network to be the state and determines whether a retransmission should be sent or not. There are many other applications of stochastic DP in communication networks [9]. Revenue management [10,11] is another important area where stochastic DP models play an important role. For example, in Bitran and Mondschein [12], authors use stochastic DP to investigate hotel room booking decisions with different customer segments and dynamic arrivals. In Green *et al.* [13], researchers use stochastic DP to study the problem of admitting different class of

patients to a diagnostic facility when emergency patients are present. In a similar study [14], authors also model patient preferences (e.g., choice of a physician and time of day for an appointment) in determining which appointment requests to admit to maximize revenue in a primary-care clinic.

It is worthwhile to mention that stochastic DP is used (recently more often) in health care, both in clinical and operational problems. For example, Patrick *et al.* [15] considers a multipriority patient scheduling model for a diagnostic resource (such as a CT scanner) to achieve priority-level target wait times in minimal cost. In Su and Zenios [16], researchers study the effect of patient choice on a kidney transplant system and the effect of the queueing discipline on organ allocation efficiency to reduce the rate of kidney refusals by patients. In another study [17], a stochastic DP model is developed to determine the number of surgeries booked for a day in the presence of both elective and emergency surgery demand. Other examples include liver transplantation decisions [18], optimal timing to start HIV therapy [19], the influenza vaccine selection [20], and optimal motion plan for the steering of an image-guided medical needle [21].

Besides the applications discussed in this article, there are many other applications of stochastic DP models in health care [22,23], finance [24], scheduling and sequencing [25], production, inventory and vehicle routing [26,27], sports [28], game theory and reinforcement learning [29–31], reliability and maintenance [32], energy [33], water reservoir systems [34], and natural resources (e.g., forestry, fisheries, and agriculture) [35]. See White [36] and Puterman [37] for more applications.

CONCLUDING REMARKS

In developing stochastic DP models, identification of the state variable is crucial. The state description should provide all the relevant information necessary for making a decision. Normally, we do not include any information that does not change from one stage to another in the state description (e.g., data) as well as the number of stages

remaining because this is implicitly present in the specification of rewards and transition probabilities.

In this article, we have focused on finite-horizon problems ($N < \infty$); however, for some applications, it makes more sense to consider infinite horizon. For infinite-horizon DPs, we need solution methods other than backward induction, although the formulations for both finite and infinite horizon models are virtually the same. For more on infinite horizon problems, refer to Puterman [3], Ross [4], and Bertsekas [38].

A major challenge in solving stochastic DPs in practice has been computational; that is, the size of the state space is too large to solve even with modern computing capabilities. This is known as *curse of dimensionality* [1,38,39]. For example, consider an inventory problem where the objective is to determine how much to keep (for a family of products) in stock to satisfy a random demand in the next N months where unsatisfied demand is lost. The objective is to maximize the expected total profit (sales revenue – inventory holding costs – ordering costs – lost sales cost). The expected revenue and cost computations depend on how much of each product type is in the inventory since some products are substitute (or complementary) of others. The decision is how much (if any) to order in each month to replenish the inventory. The state variable for this problem should include the inventory on hand for each product i . Suppose the capacity (of the storage facility per product family) is C , then the state is vector $s_n = (q_1, q_2, \dots, q_m)_n$ where $0 \leq q_i \leq C$ for $i = 1, 2, \dots, m$ and $n = 1, 2, \dots, N$. Suppose $m = 7$ and $C = 10$, then the state space contains 10^7 terms. (In recent decades, a field of research called *approximate dynamic programming* [38] has developed in an attempt to solve larger models.)

One of the advantages of the DP framework is that it is often possible to obtain a structure for an optimal policy. Establishing such a structure for the optimal policy is desirable because it provides managerial and intuitive insight into the problem. Furthermore, with structure, computation of the optimal policy can often be simplified.

STOCHASTIC GRADIENT METHODS FOR SIMULATION OPTIMIZATION

MICHAEL C. FU
University of Maryland,
College Park, Maryland

INTRODUCTION

Stochastic gradient methods refer to techniques for estimating gradients from sample paths or simulation replications. Often, a distinction is made between what are known as direct versus indirect methods. Indirect methods estimate an approximation to the gradient—usually a form of secant based on finite differences, whereas direct methods refer to approaches that estimate the actual gradient—geometrically, the tangent vector. Direct methods generally provide an unbiased estimator for the gradient, whereas indirect methods are biased, with the bias generally vanishing as the difference used in the estimator goes to zero. However, the efficiency of the estimators depends not only on the bias but also the amount of computation required and the precision of the estimate, usually measured in terms of variance. In settings in which they are applicable, direct estimators can be far more efficient than indirect estimators. This article deals only with direct estimators.

Two areas in which gradients play a central role are sensitivity analysis and optimization. For simulation optimization, gradient estimators can be used in algorithms that exploit gradient information, such as those based on stochastic approximation. For example, if we are trying to minimize a function $J(\theta)$, as a function of the parameter (vector) θ , then the stochastic approximation algorithm takes the following general form:

$$\theta_{n+1} = \theta_n - a_n \widehat{\nabla J}(\theta),$$

where θ_n denotes the n th iterate of the parameter, $\{a_n\}$ is a sequence of step-size multipliers, and $\widehat{\nabla J}(\theta)$ denotes an estimate of the gradient $\nabla J(\theta)$. Clearly, the effectiveness of the algorithm rests heavily on the quality of the gradient estimate. In general, the two desirable properties are those of any statistical estimator: low bias and low noise, sometimes combined into a single mean-squared error measure. Specifically, here we seek unbiased estimators

$$E[\widehat{\nabla J}(\theta)] = \nabla J(\theta),$$

with low variance.

This article describes the two most well-known approaches for stochastic gradient estimation:

- perturbation analysis (PA),
- likelihood ratio method (LRM), which is also called the score function method.

Specifically, the focus is on presenting the ideas of infinitesimal perturbation analysis (IPA) and the LR method (LRM); they are illustrated with examples from the main application areas of queueing, inventory, and finance. Other approaches not described here are based on Malliavin calculus, weak derivatives or WD (also called measure-valued differentiation), simultaneous perturbations, and frequency domain experimentation; the latter two approaches are more akin to indirect methods since they involve actual changes in the underlying parameter values. *Neither IPA nor LRM estimators require any alteration in the parameter settings of the simulation model.*

IPA AND LRM

Let $J(\theta)$ denote a *performance measure* that depends on a vector of *parameters* θ , where it is assumed that there is some *sample* performance $L(\theta, \omega)$ such that $J(\theta) = E[L(\theta, \omega)]$, with ω denoting a sample path or simulation replication. In terms of simulation, ω

could represent all of the random number seeds required to generate a single sample path. Common sample performance measures include

- queueing—average time in queue, average number in system, percentage of customers who wait in queue for more than a certain prescribed limit;
- inventory—long-run average holding, ordering and/or backlogging costs; percentage lost sales, percentage demand met from on-hand inventory;
- finance—profit/loss profile or terminal wealth in investment/portfolio management; (discounted) payoff from a derivatives contract.

Parameters of interest can be divided into two main classes:

- distributional—for example, the mean of interarrival and service times in a queueing system, mean of demand in an inventory system, the mean return and volatility of a stock in a finance problem;
- structural—for example, the upper bound target wait time in a queueing system, the reorder point and order quantities in inventory control, the knock-in or knock-out values in barrier options (finance).

The type of parameter is usually clear from the context but in some cases, the distinction is unclear or arbitrary, and depending on the formulation (or reformulation) a parameter could be viewed as either type. The focus of the exposition here will be on distributional parameters.

Although most performance measures of interest are expectations, including probabilities as special cases by using indicator functions, quantiles

$$q_\alpha = \min_x \{P(L \leq x) \geq \alpha\}, \quad 0 \leq \alpha \leq 1,$$

cannot be captured by expectations. Quantiles will not be treated here, but the reader is referred to the final section titled “Probing

Further” for references and applications of PA to this setting.

By the definition of expectation, the calculation of $E[L]$ requires knowing the distribution of L . However, the *raison d’être* for using stochastic simulation is that this distribution is not easy to get a handle on. Basically, the distribution is available *implicitly*, in that the simulation model generates samples from the distribution of the output performance measure using samples from the input distributions/processes. In the dynamic setting, these are called sample paths, or in simulation terminology, simulation replications or sometimes, realizations. For example, in queueing, the inputs are generally input and service time processes, for which the simulation model generates sample paths of the number in queue and waiting time processes.

To be more precise, the expectation is written in two ways, first using the formal definition of expectation and then using the elementary result for the expectation of a function of random variables:

$$E[L(X)] = \int y \, dF_L(y) = \int \dots \int L(x) \, dF_X(x), \quad (1)$$

where X is a *vector* of all the input random variables used in the simulation, F_L is the distribution of the univariate output sample performance measure L , F_X is the (joint) distribution of X , and the second integral has dimension corresponding to the number of input random variables (dimension of the vector X). As mentioned already, F_L is not known explicitly; else, simulation would not be needed. However, in simulation, F_X is usually known, because it is used to generate the input process to the simulation model; for example, interarrival and service times in a queueing system. In probability theory, this is a basic result of computing the expectation of a function of random variables, called the “law of the unconscious statistician” in the well-known textbook, “Stochastic Processes,” by Sheldon Ross ([1], although the terminology seems to have been removed in the second edition; see also Ross [2]), evidently reflecting that many people use the result as if it were the definition of expectation rather than

an elementary result. In any case, stochastic simulation can be viewed as carrying out the “law of the unconscious statistician” using a simulation model to generate output samples $L(X)$ from input samples X .

Note the parameter θ has not been placed anywhere in expression (1). In fact, where it is placed is what “differentiates” IPA and LRM. To simplify the exposition, henceforth θ will be assumed to be a scalar since in the vector case, the gradient can be obtained by finding each of the partial derivatives individually, so there is no loss of generality in making this assumption. Thus, the problem is to estimate

$$\frac{dE[L]}{d\theta} \quad (2)$$

using simulation.

A “brute-force” finite difference (indirect) estimate is obtained by doing additional simulations at parameter value $(\theta + \Delta\theta)$, subtracting from these samples of L the simulation estimates of L at the original parameter value θ , and then dividing by the perturbation $\Delta\theta$. However, if the number of parameters is large (e.g., large number of decision variables in an optimization problem), then this could entail a large number of additional simulations. Moreover, selecting the value for $\Delta\theta$ entails a trade-off between variance and bias, where larger $\Delta\theta$ generally means lower variance but higher bias when the goal is to estimate the value of Equation (2). The order of the bias can be decreased by using symmetric differences, that is, simulate at both $(\theta + \Delta\theta)$ and $(\theta - \Delta\theta)$, but the downside is that this would require basically doubling the number of simulations.

Research starting from the 1980s has resulted in developing accurate and efficient *direct* ways to estimate derivatives from simulation. Returning to the placement of θ , consider the following two cases:

$$E[L(X)] = \int_0^1 \dots \int_0^1 L(X(\theta; u)) du, \quad (3)$$

$$E[L(X)] = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x) dF_X(x; \theta). \quad (4)$$

The first case—corresponding to IPA—views the underlying randomness as a vector of random numbers generating the input random variables X depending on the parameter θ , whereas the second case—corresponding to LRM—takes θ as a parameter in the (joint) distribution F_X of all of the input random variables. Another version of the first case (IPA) not considered explicitly here is

$$E[L(X)] = \int_0^1 \dots \int_0^1 L(X(u); \theta) du,$$

where the parameter does not enter into the input random variables but directly into the sample performance. This is the structural parameter case mentioned earlier, with an example being the upper bound target wait time in a queueing system.

To illustrate the ideas more concretely, consider a specific example involving just two input random variables, assumed to be generated independently, with $X_1 \sim \exp(\theta)$ and $X_2 \sim U(0, 1)$; that is, the first random variable is exponentially distributed with mean θ and the second is uniformly distributed over $[0, 1]$. Then Equations (3) and (4) are written respectively as

$$E[L(X)] = \int_0^1 \int_0^1 L(X_1(u_1; \theta), u_2) du_1 du_2, \quad (5)$$

where $X_1(u; \theta) = -\theta \ln u$ is the common method of generating samples from the distribution $\exp(\theta)$, and

$$E[L(X)] = \int_0^1 \int_0^{\infty} L(x_1, x_2) \frac{1}{\theta} e^{-x_1/\theta} dx_1 dx_2. \quad (6)$$

Differentiating Equations (5) and (6), assuming that the differentiation operator can be brought inside the integrals (conditions under which this is permitted are discussed in the section titled “Unbiasedness: Validity of the Interchange”):

$$\begin{aligned} \frac{dE[L(X)]}{d\theta} &= \int_0^1 \int_0^1 \frac{\partial L(X_1(u_1; \theta), u_2)}{\partial X_1} \\ &\quad \times \frac{dX_1(\theta; u_1)}{d\theta} du_1 du_2, \end{aligned} \quad (7)$$

and for the second case,

$$\begin{aligned} \frac{dE[L(X)]}{d\theta} &= \int_0^1 \int_0^\infty L(x_1, x_2) \left[\frac{1}{\theta} \left(\frac{x_1}{\theta} - 1 \right) \right] \\ &\quad \times \frac{1}{\theta} e^{-x_1/\theta} dx_1 dx_2, \end{aligned} \quad (8)$$

with respective IPA and LRM estimators corresponding to Equations (7) and (8):

$$\frac{\partial L(X_1, X_2)}{\partial X_1} \frac{dX_1}{d\theta}, \quad L(X_1, X_2) \left[\frac{1}{\theta} \left(\frac{X_1}{\theta} - 1 \right) \right].$$

To finalize the first estimator requires knowing something about the *specific form* of L (to calculate the first factor) and defining the *derivative of a random variable* with respect to a parameter (to calculate the second factor); intuitively, though, differentiating $X_1(u; \theta) = -\theta \ln u$ gives $\frac{dX_1(u; \theta)}{d\theta} = -\ln u = \frac{X_1(u; \theta)}{\theta}$. The second estimator can be implemented *without any further knowledge or simulation* over what is required to estimate the original performance measure by $L(X_1, X_2)$; that is, the original performance measure estimator is simply multiplied by a “weight” function. This simple example contains the main ingredients of the general case.

Returning to the more general settings of Equations (3) and (4), again differentiating each, assuming an interchange of integration and differentiation is permissible,

$$\frac{dE[L(X)]}{d\theta} = \int_0^1 \dots \int_0^1 \frac{dL(X(\theta; u))}{d\theta} du, \quad (9)$$

and

$$\frac{dE[L(X)]}{d\theta} = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x) \frac{\partial f(x; \theta)}{\partial \theta} dx, \quad (10)$$

where f is the (joint) density corresponding to F_X . For expositional ease in introducing the approaches, begin by assuming that the parameter only appears in X_1 , which is generated *independently* of the other input random variables. So for the case of Equation (9), use

the chain rule to write

$$\begin{aligned} \frac{dE[L(X)]}{d\theta} &= \int_0^1 \dots \int_0^1 \frac{dL(X_1(\theta; u_1), X_2, \dots)}{d\theta} du \\ &= \int_0^1 \dots \int_0^1 \frac{\partial L}{\partial X_1} \frac{dX_1(\theta; u_1)}{d\theta} du. \end{aligned} \quad (11)$$

In other words, the IPA estimator takes the same general form as before:

$$\frac{\partial L(X)}{\partial X_1} \frac{dX_1}{d\theta}, \quad (12)$$

where the parameter appears in the transformation from random number to random variate, and the derivative is expressed as the product of a sample path derivative and derivative of a random variable.

Assume that X_1 has marginal p.d.f. $f_1(\cdot; \theta)$ and that the joint p.d.f. for the remaining input random variables $(X_2, \dots)$ is given by f_{-1} , which has no (functional) dependence on θ . Then the assumed independence gives $f = f_1 f_{-1}$, and the expression (10) involving differentiation of a density (measure) can be further manipulated using the product rule of differentiation to yield the following:

$$\begin{aligned} \frac{dE[L(X)]}{d\theta} &= \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x) \frac{\partial f_1(x_1; \theta)}{\partial \theta} f_{-1}(x_2, \dots) dx \\ &= \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x) \frac{\partial \ln f_1(x_1; \theta)}{\partial \theta} f_1(x_1; \theta) \\ &\quad \times f_{-1}(x_2, \dots) dx \\ &= \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x) \frac{\partial \ln f_1(x_1; \theta)}{\partial \theta} f(x) dx. \end{aligned}$$

In other words, the LRM estimator takes the form

$$L(X) \frac{\partial \ln f_1(X_1; \theta)}{\partial \theta}, \quad (13)$$

where the second factor in Equation (13) is called the score function in statistics.

The IPA estimator (12) requires the notion of a derivative of a random variable, which intuitively coincides with the definition of a derivative in the usual sense by defining the

limiting difference on a common probability space and fixing the sample outcome. Several useful cases are now presented, where here X represents a single random variable.

- Assuming the existence of a density:

$$\frac{dX}{d\theta} = -\frac{\partial F(x; \theta)/\partial \theta}{\partial F(x; \theta)/\partial x} \Big|_{x=X}, \quad (14)$$

where F is the cumulative distribution function of X , so the denominator is simply the probability density function [3], [4].

- For a *location*, *scale*, or *generalized scale* parameter, defined here in terms of the random variable rather than the distribution:
- θ is a *scale* parameter for X if there exists a random variable Z that has no dependence on θ such that $X = Z\theta$ with probability 1. Then,

$$\frac{dX}{d\theta} = \frac{X}{\theta}.$$

An example is the exponential distribution, for which the mean is a scale parameter, verifying the result $\frac{dX}{d\theta} = \frac{X}{\theta}$ that was intuitively derived earlier through direct differentiation of the expression $X(u, \theta) = -\theta \ln u$, and which could also be derived using Equation (14). Another scale parameter example is $U(0, \theta)$.

- θ is a *location* parameter for X if there exists a random variable Z that has no dependence on θ such that $X = Z + \theta$ with probability 1. Then,

$$\frac{dX}{d\theta} = 1.$$

An example is the mean of a uniform distribution, that is $U(\theta - \delta, \theta + \delta)$. Note that the mean is not a location parameter in the previous example where θ is parameterized as $U(0, \theta)$.

- θ is a *generalized scale* parameter for X if there exist a constant $\bar{\theta}$ and a random variable Z that have no

dependence on θ such that $X = \bar{\theta} + Z\theta$ with probability 1. Then,

$$\frac{dX}{d\theta} = \frac{X - \bar{\theta}}{\theta}.$$

An example is the spread of a uniform distribution, that is $U(\bar{\theta} - \theta, \bar{\theta} + \theta)$.

Nearly every distribution has at least one parameter that is location or (generalized) scale, and many have both (e.g., normal, Cauchy, Gumel, logistic, general uniform).

To illustrate the ideas concretely, consider two sample performance functions of two random variables, this time without specifying the actual distributions.

Example 1. $L(X) = X_1 + X_2$.

- IPA estimator:

$$\frac{dX_1}{d\theta} + \frac{dX_2}{d\theta},$$

regardless of any dependence between X_1 and X_2 .

- LRM estimators:

$$(X_1 + X_2) \frac{\partial \ln f(X_1, X_2; \theta)}{\partial \theta},$$

for the general bivariate case, and

$$(X_1 + X_2) \left(\frac{\partial \ln f_1(X_1; \theta)}{\partial \theta} + \frac{\partial \ln f_2(X_2; \theta)}{\partial \theta} \right),$$

for the independent case.

Example 2. $L(X) = \max(X_1, X_2)$.

- IPA estimator:

$$\frac{dX_1}{d\theta} \mathbf{1}_{\{X_1 > X_2\}} + \frac{dX_2}{d\theta} \mathbf{1}_{\{X_1 < X_2\}},$$

regardless of any dependence between X_1 and X_2 , but generally unbiasedness requires $P(X_1 = X_2) = 0$ (e.g., when both are continuous random variables), due to the discontinuity at $X_1 = X_2$.

- LRM estimators:

$$\max(X_1, X_2) \frac{\partial \ln f(X_1, X_2; \theta)}{\partial \theta},$$

for the general bivariate case, and

$$\max(X_1, X_2) \left(\frac{\partial \ln f_1(X_1; \theta)}{\partial \theta} + \frac{\partial \ln f_2(X_2; \theta)}{\partial \theta} \right),$$

for the independent case.

In both examples, notice that the LRM estimators do not depend on the form of the sample performance, but on the number of random variables involved. Also, the simple examples illustrate that where the parameter appears is in some sense under the control of the modeler/analyst. So a service time parameter can be viewed as a parameter of the underlying distribution generating the service time random variate, or it can be viewed as a parameter directly influencing the value of the service time random variable itself, where the underlying uncertainty is simply a stream of random numbers. In some cases, the parameter could even appear in both places at the same time.

Generalizing these two examples leads to the following general forms of estimators, where the parameter can possibly occur in every input random variable (otherwise, that term is simply zero):

- IPA estimator:

$$\sum_i \frac{\partial L(X)}{\partial X_i} \frac{dX_i}{d\theta},$$

- LRM estimators: (multivariate, independent)

$$L(X) \frac{\partial \ln f(X; \theta)}{\partial \theta}, \quad L(X) \sum_i \frac{\partial \ln f_i(X_i; \theta)}{\partial \theta}.$$

PRACTICAL GUIDELINES

This section provides brief guidelines on the challenges and implementation of the two approaches.

Challenges

- LRM is likely to encounter computational challenges in the case where the same parameter recurs; for example, if the simulation model involves i.i.d. input random variables where θ is a parameter in the common distribution. Examples include service times or interarrival times in queueing and customer demands in inventory control. More details are provided below when implementation is discussed.
- The main requirement for IPA to succeed is that the sample performance be continuous with respect to the parameter of interest. Although technically this is only a sufficient and not necessary condition (i.e., it is not difficult to construct examples where IPA works for discontinuous sample performances), for all practical purposes this is also a necessary condition. In practice, a discontinuity manifests itself in two principal forms: inherently discontinuous sample performances, for example probability performance measures (where the sample performances are indicator functions), or any performance measure whose sample performance is discrete-valued (except in the trivial case where it is constant as a function of the parameter of interest); and simulation models where small changes in the parameter of interest could cause an abrupt change in system behavior such as a different event to occur; for example, a customer in a queueing system balking rather than being served.
- LRM may encounter difficulties in handling *structural* parameters, such as inventory control parameters, although a change of variables sometimes can be used to move the parameter into a distribution. The ability to move the parameter into or out of the underlying input distributions are sometimes referred to as “push-out” and “push-in” methods.
- LRM cannot handle parameters that change the underlying support of the distribution.

- For *discrete* distributions, IPA works if the parameter occurs in the support *values*, whereas LRM works if the parameter occurs in the support *probabilities*.
- *Higher derivative* estimates are generally easier to derive using LRM, though the variance of the resulting estimators may be problematic. A combination of two approaches might lead to an estimator with improved variance; for example, IPA for the first derivative and then LRM for the second derivative, or vice versa.

Implementation

- Implementation of the LRM estimator is usually the most straightforward. However, if the input process involves i.i.d. random variables whose common distribution depends on the parameter of interest, then the *variance of the estimator will grow linearly* with the number of times that random variable is used in the simulation, so the estimator can quickly become practically useless. This difficulty can be mitigated by batching; for example, rather than averaging over 1000 customers, take an average of 100 samples of 10 customers each. Using regenerative cycles is another way around the problem.
- Implementation of the IPA estimator generally requires *further knowledge of the dynamics of the system*, essentially to be able to implement the $\partial L / \partial X_i$ portion of the chain rule, where X_i is the input random variable through which the parameter dependence enters. In many cases of practical interest, this is not difficult to implement, and the additional computational burden is relatively minimal.

UNBIASEDNESS: VALIDITY OF THE INTERCHANGE

Justifying the exchange of differentiation (limit) and expectation operators required in Equations (9) or (10) can be equated with the concept of uniform integrability,

which is a necessary and sufficient condition. However, since uniform integrability is impossible to verify in practical applications, the key result used in the theoretical proofs of unbiasedness is the (Lebesgue) dominated convergence theorem.

For IPA, a sufficient condition is that the sample performance be continuous with respect to the parameter, which translates into requirements on the form of the performance measure and on the dynamics of the underlying stochastic system. A nice set of sufficient conditions that is often used requires Lipschitz continuity. In the framework of generalized semi-Markov processes (GMSPs) as a model for stochastic discrete-event simulation, the so-called “commuting condition” provides a useful set of structural conditions for checking the dynamics of the underlying system.

For LRM, the bounding condition in the dominated convergence theorem is applied to the (joint) density (or mass) function, where the bound is for $f(x; \theta)$ with respect to the parameter θ and not its usual argument x . This is more intuitively viewed as a requirement of absolute continuity of $f(\cdot; \theta + \Delta\theta)$ with respect to $f(\cdot; \theta)$, whereby for all x , if $f(x; \theta) = 0$, then $f(x; \theta + \Delta\theta) = 0$. A simple example illustrates how difficulties may arise. Consider the $U(0, \theta)$ probability density function

$$f(x; \theta) = \frac{1}{\theta} \mathbf{1}\{0 < x < \theta\},$$

where LRM does not apply. In this case, f viewed as a function of θ for fixed x has a discontinuity at $\theta = x$; in terms of absolute continuity, for $\Delta\theta > 0$, at the point $x = \theta + \Delta\theta/2$, the function fails to be absolutely continuous, since $f(\theta + \Delta\theta/2; \theta) = 0$, but $f(\theta + \Delta\theta/2; \theta + \Delta\theta) = 1/(\theta + \Delta\theta)$.

Smoothed Perturbation Analysis: An Extension of IPA

When IPA fails, numerous extensions have been proposed; thus, the term “perturbation analysis” actually refers to all of these different approaches and not just IPA; references for other PA techniques are given in the final section. This section briefly introduces the

most developed extension called smoothed perturbation analysis (SPA), which is based on conditional Monte Carlo, a well-known variance reduction technique in stochastic simulation in which the idea is to choose a random variable (or set of random variables), represented here by Z , such that

- (a) $E[L|Z]$ is easily computable;
- (b) $\text{Var}(E[L|Z])$ is small.

In variance reduction applications, it can be shown that $\text{Var}(E[L|Z]) \leq \text{Var}L$, so conditional Monte Carlo estimators are guaranteed to do no worse in terms of variance (this does not consider the additional computation that might be required).

Analogously, the main idea of SPA is to choose Z such that

- (a) $\frac{d}{d\theta}E[L|Z]$ is easily computable;
- (b) $E\left[\frac{d}{d\theta}E[L|Z]\right] = \frac{d}{d\theta}E[E[L|Z]] = \frac{dE[L]}{d\theta}$.

Thus, the main challenges in applying SPA are (i) the choice of what to condition on and (ii) how to compute (estimate) the resulting conditional expectation derivative. Challenge (ii) may lead to many additional simulations.

To demonstrate how this works for the two simple examples, consider a probability performance measure, that is $P(L(X) \leq x)$ for some fixed x , for which IPA fails because the sample performance is an indicator function. For simplicity of exposition, take the case where the two random variables are independent and assume θ enters into the distribution of the first random variables X_1 . For $L(X) = X_1 + X_2$, noting that $P(X_1 + X_2 \leq x) = E[\mathbf{1}\{X_1 + X_2 \leq x\}]$, simply condition on the other random variable:

$$\begin{aligned} E[\mathbf{1}\{X_1 + X_2 \leq x\}|X_2] &= P(X_1 \leq x - X_2|X_2) \\ &= F_1(x - X_2; \theta), \end{aligned}$$

where F_1 is the cumulative distribution function for X_1 . Differentiating gives the density as the SPA estimator:

$$\frac{d}{d\theta}E[\mathbf{1}\{X_1 + X_2 \leq x\}|X_2] = f_1(x - X_2; \theta).$$

Similarly, for the other sample performance $L(X) = \max(X_1, X_2)$,

$$\begin{aligned} E[\mathbf{1}\{\max(X_1, X_2) \leq x\}|X_2] \\ &= P(X_1 \leq x|X_2 \leq x)\mathbf{1}\{X_2 \leq x\} + 0 \cdot \mathbf{1}\{X_2 > x\} \\ &= F_1(x; \theta)\mathbf{1}\{X_2 \leq x\}, \end{aligned}$$

and differentiating gives the SPA estimator:

$$f_1(x; \theta)\mathbf{1}\{X_2 \leq x\}.$$

APPLICATIONS

As mentioned earlier, the three main operations research/management science application areas for stochastic gradient estimation have been queueing systems, production/inventory systems, and finance. Some simple illustrative examples are provided for each. Chronologically, the first application area was queueing systems, which dominated the research focus for almost two decades; since queueing networks can be used to model so many different classes of large-scale systems, including communications networks, manufacturing systems, supply chains, or transportation network/systems, queueing network simulation models cover a huge range of applications. Applications to inventory control and financial engineering began in the 1990s.

Queueing

Application of IPA and LRM will be illustrated using the simplest queueing example—a first-come, first-served single-server queue, taking the (sample) performance measure as the waiting time (in queue) of the n th customer ($n > 1$), denoted by W_n , with the parameter θ in the service time distribution, where X_i denotes the service time of the i th customer. To be concrete, take θ as the mean of an exponential distribution.

First consider the case where the parameter θ affects only a single service time, specifically $X_{n-1} \sim \exp(\theta)$, giving the following estimators for $\frac{dE[W_n]}{d\theta}$:

- IPA

$$\frac{dX_{n-1}}{d\theta}\mathbf{1}\{W_n > 0\} = \frac{X_{n-1}}{\theta}\mathbf{1}\{W_n > 0\},$$

which reflects the notion that the service time of a customer only affects the waiting times of subsequent customers in the same busy period, where the condition $W_n > 0$ implies that the n th and $(n - 1)$ th customer are in the same busy period.

- LRM

$$\frac{W_n}{\theta} \left(\frac{X_{n-1}}{\theta} - 1 \right).$$

Now consider the case where the parameter affects all of the service times, specifically θ is the common mean for the i.i.d. exponentially distributed service times $\{X_i\}$, which leads to the following estimators for $\frac{dE[W_n]}{d\theta}$:

- IPA

$$\sum_{n^* \leq i < n} \frac{dX_i}{d\theta} = \sum_{n^* \leq i < n} \frac{X_i}{\theta},$$

where n^* denotes the index of the customer that begins the busy period of customer n , so the sum is empty if customer n begins the busy period.

- LRM

$$\frac{W_n}{\theta} \sum_{i < n} \left(\frac{X_i}{\theta} - 1 \right),$$

which basically has variance proportional to n .

Although the straightforward LRM estimator is computationally prohibitive for large n , by utilizing the independence of W_n from service times before the start of customer n 's busy period, which is done implicitly in the IPA estimator, the variance problem can be ameliorated. In other words, for $i < n^*$, $E[W_n X_i] = E[W_n]E[X_i] \implies E[W_n(X_i/\theta - 1)] = 0$, so a much-improved LRM estimator with the same expected value is given by

$$\frac{W_n}{\theta} \sum_{n^* \leq i < n} \left(\frac{X_i}{\theta} - 1 \right).$$

This illustrates one way in which regeneration can be used to mitigate potential variance problems in LRM estimators.

Inventory

Inventory control is the second class of applications to which derivative estimation has been successfully applied. When simulating inventory control systems utilizing base-stock policies, IPA estimators can be easily implemented, and if the sample performance is continuous with respect to the base-stock level—often the case in practice—the resulting IPA estimators are unbiased. Difficulties arise when setup costs are included in the model, requiring a two-parameter order policy with a reorder point and order quantity or order-up-to level, because small changes in one of the parameters can cause discontinuities in the sample path. To illustrate the challenge, consider an (s, S) inventory control example, where s is the reorder point and S is the order-up-to point. Rather than the usual parameters s and S , the parameters of interest will be s and $q = S - s$, where the latter can be viewed as the (approximate) order quantity. The sample paths will show intuitively the continuity with respect to changes in s for q held constant, whereas there are discontinuities with respect to changes in q with s held constant. As a result, IPA estimators will be unbiased for performance measures with respect to s (with q held constant), whereas they would be biased for performance measures with respect to q , and SPA estimators would be required.

Figure 1 shows two sample paths of the inventory position, where the vertical lines indicate the order decision points at the end of each period. Thus, if the inventory position is below the reorder point s , then an order up to S is placed. The bolder path is the original sample path—called the *nominal path* in PA literature, whereas the lighter path—called the *perturbed path*—is the path after the perturbation by Δs with q held constant, which results in S also being increased by Δs . The key in the sample path analysis is that discontinuities in going from the nominal path to the perturbed path can only occur at the reorder points if an order decision becomes a no-order decision or vice versa. In Figure 1, there is an order placed at the end of period n in the nominal path, and there is also an

Figure 1. IPA is easy for (s, S) inventory system for the derivative with respect to s , assuming q held fixed, because the distance of the inventory position from the reorder point is the same in the perturbed (lighter) and the original (bolder) sample paths, as indicated by arrows.

order placed at the end of period n in the perturbed path. Most importantly, the distance of the inventory position from the reorder point is unchanged before and after the perturbation, *regardless of the size (and sign) of the perturbation*, and thus the perturbed path is simply the nominal path changed by Δs .

Figure 2 shows two analogous sample paths when s is kept constant, but q is increased by $\Delta q > 0$. In the case shown, Δq is sufficiently large so that the perturbed path ends up not ordering at the end of period n , which results in a drastic divergence from the original (nominal) sample path, resulting in a discontinuity in a sample performance defined on the process.

Finance

In financial risk management, hedging of contracts is a key focus, and gradients play the central role in executing any hedging strategy. These gradients are called the “Greeks” in finance, because Greek letters are used to represent the various partial derivatives (sensitivities). For example, the most famous ones include the “delta,” “vega,” and “rho,” which are the sensitivities of the price with respect to the underlying asset price, the underlying asset’s volatility, and the interest rate, respectively. As pointed out in the Lancaster Prize-winning book by Glasserman, *Monte Carlo Methods in Financial Engineering* (p. 377):

Figure 2. IPA fails for (s, S) inventory system for the derivative with respect to q (or S), assuming s held fixed, because a positive perturbation can cause an order decision in the original (bolder) path to become a no-order decision in the perturbed (lighter) path.

“Whereas the prices themselves can often be observed in the market, their sensitivities cannot, so accurate calculation of sensitivities is arguably even more important than calculation of prices.”

As mentioned previously, application of gradient estimation methods in simulation to the finance setting did not occur until the mid 1990s, and probably did not become known in the finance community until after the turn of the century, as indicated by the fourth (2000) edition of a very popular textbook by John Hull [5] on derivatives pricing, *Options, Futures, and Other Derivatives Securities* (p. 410):

“Suppose that we are interested in the partial derivative of f with q , where f is the value of the derivative and q is the value of an underlying variable or a parameter. First, Monte Carlo simulation is used in the usual way to calculate an estimate, f , for the value of the derivative. A small increase, Δq , is then made in the value of q , and a new value for the derivative, f^* , is calculated. An estimate for the hedge parameter is given by

$$\frac{f^* - f}{\Delta q}$$

In order to minimize to [sic] standard error of the estimate of the Greek letter, the number of time intervals, N , the random number streams, and the number of trials, M , should be the same for estimating both f and f^* .”

Simulation is widely used on Wall Street and throughout the financial industry worldwide, and the techniques discussed in this article can be used to obtain estimates of the sensitivities with respect to various parameters without resimulation. In both pricing and hedging of derivatives contracts, the final problem usually comes down to an optimization problem. For hedging, one usually tries to minimize some (expected or probability of) deviation from a target payoff (or path of payoffs), whereas for pricing, the optimization problem is generally to maximize the expected payoff in a classical optimal stopping problem. With regards to pricing, the second (1993) edition of the previously mentioned textbook by John Hull had this to say:

“Monte Carlo simulation can only be used for European-style options.”

However, research advances in developing simulation algorithms for pricing American-style derivatives has led to this statement being tempered to “... cannot easily handle situations where there are early exercise opportunities” and actually including material describing some of the approaches. One of the simulation approaches that has been developed uses gradient-based stochastic optimization, where the decision of whether or not to exercise an option is made according to a decision rule that is defined by a parameterized exercise boundary, and thus gradients with respect to the parameters are central to the method.

To illustrate the ease with which these estimators can be implemented, consider a simple European call stock option with payoff given by

$$(S_T - K)^+,$$

where S_t denotes the stock price at time t , T is the expiration time of the option, and K is the strike price. The option price is given by the expectation of the discounted payoff, where here the discounting assumes a constant risk-free continuous interest rate r . The delta of this option is the sensitivity with respect to the current stock price S_0 :

$$\frac{d}{dS_0} E \left[e^{-rT} (S_T - K)^+ \right].$$

The IPA estimator is straightforward to obtain, although the final form will depend on the form of the underlying stock price model. To apply LRM, the “parameter” of interest S_0 has to be incorporated into the underlying distribution of S_T . How this is done also depends on the underlying stock price model. For the Black–Scholes (geometric Brownian motion process, lognormally distributed) stock price model with volatility σ , the respective IPA and LRM estimators for the option delta are given by

$$e^{-rT} \frac{S_T}{S_0} \mathbf{1}_{\{S_T > K\}}, \quad e^{-rT} (S_T - K)^+ \frac{Z}{S_0 \sigma \sqrt{T}},$$

where $Z \sim N(0, 1)$ is the standard normal random variate used to generate S_T from S_0 via

$$S_T = S_0 e^{(r - \sigma^2/2)T + \sigma\sqrt{T}Z}.$$

The form of the IPA estimator remains unchanged for stock price models in which the current stock price acts as a scale parameter for the future stock price, for example exponential Lévy processes.

SUMMARY

The main message is that when conducting stochastic simulation, efficient gradient estimates can often be easily obtained from the original simulation just by doing a little extra calculation and *without having to alter any model parameter settings*. These gradient estimates can be used in gradient-based simulation optimization, which can take many different forms, from stochastic approximation to sequential response surface methodology to sample average approximation based on nonlinear deterministic optimization formulations.

LRM requires knowledge of the distributions that serve as inputs to the simulation model. In most settings, these are known and thus, it is relatively easy to obtain sensitivity estimates. IPA is more restrictive, because its applicability depends on properties of both the system model and the performance measure(s) of interest. In cases where both techniques can be applied, the IPA estimate usually has lower variance.

Because of the more limited applicability of IPA, there has been an abundance of research to extend its applicability, resulting in numerous other techniques that are more specialized and problem dependent and sometimes requiring additional simulations. The most generally applicable of these is SPA, which is based on conditional Monte Carlo, relying on the “smoothing” property of conditional expectation to allow the interchange in Equation (9).

PROBING FURTHER

A large part of the exposition here is excerpted and condensed from the cover article, [6], which also discusses estimators based on weak derivatives (WD); for a recent survey of the latter, see Heidegott [7]. A further in-depth discussion can be found in the handbook chapter by Fu [8]. Both references include a table for implementing many commonly used input probability distributions in IPA, LRM, or WD estimators. Treatment at a similar level for the more general PA is presented in Fu *et al.* [9] and for the more general “score functions” in Rubinstein *et al.* [10].

Recent books on simulation containing extensive coverage of gradient estimation include Glasserman [11], Chapter 7, which treats both IPA and LRM in the finance setting, although IPA is called the “pathwise” method there, which seems to have become the generally accepted nomenclature in finance; Chapter VII of Asmussen and Glynn [12], which also includes both IPA and LRM estimators; and Chapter 11 of the broader discrete-event systems textbook by Cassandras and Lafortune [13], which includes coverage of IPA, SPA, and finite perturbation analysis (FPA). Earlier books focusing on specific gradient estimation approaches include Ho and Cao [14], Glasserman [4], and Cao [15] for IPA, and Rubinstein and Shapiro [16] for LRM, where it is called the score function method; see also Rubinstein and Melamed [17]. A detailed discussion of the “commuting condition” for IPA can be found in Glasserman [4].

As pointed out early in the discussion, IPA is just one method—albeit the most common and easily implementable technique—in the vast PA arsenal that has been developed over many decades. The main idea behind the PA approach is to study the effect on the sample performance when a parameter value is perturbed slightly; however, in most PA methods, the parameter is never actually altered in either the analysis or in the simulation, for example IPA can be viewed as the limiting case when the size of the perturbation vanishes. Using conditional Monte Carlo to extend IPA’s applicability

in the framework of SPA was introduced by Gong and Ho [18], though the conditioning idea was also used in Suri and Zazanis [3], and the book by Fu and Hu [19] covers SPA in full generality, including numerous application areas. Other PA techniques include rare perturbation analysis (RPA), originally based on the thinning of point processes [20]; structural infinitesimal perturbation analysis (SIPA), dealing specifically with structural parameters [21]; discontinuous perturbation analysis (DPA), based on the use of generalized functions (the Dirac-delta function) to model discontinuities in the sample performance function [22]; and augmented infinitesimal perturbation analysis (APA), another extension of IPA different from SPA [23]. Techniques to estimate the effect of a *finite* perturbation in the parameter value include FPA [24]; extended perturbation analysis (EPA) [25]; and the augmented chain method [26]. A related technique is the standard clock (SC) method, based on the uniformization of Markov chains [27].

As pointed out several times, it is theoretically possible for θ to appear simultaneously in two places, for example,

$$E[L(X)] = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} L(x; \theta) dF(x; \theta).$$

A theoretical framework for such a “unified” view of IPA and LRM was presented in L’Ecuyer [28], where a few simple examples are presented. Recently Wang *et al.* [29,30] have demonstrated practical examples arising naturally in finance applications where the “push-in/push-out” change of variables technique described in Rubinstien and Shapiro [16] for LRM can be used to derive a hybrid IPA/LRM estimator in a situation where neither IPA nor LRM is applicable by itself.

Besides queueing, inventory, and finance, other applications include stochastic activity networks, preventive maintenance, statistical process control, and traffic light control; for specific references, see Fu [8], which also contains sources for those approaches mentioned in the introduction not covered in this article: Malliavin calculus, WD, simultaneous perturbations, and frequency domain

experimentation. Not included there are the more recent developments for quantiles, which include Hong [31] for IPA and Fu *et al.* [32] for SPA, and also the connection between LRM and the Malliavin calculus approach in Chen and Glasserman [33].

For more on gradient-based simulation optimization applications and issues, see Fu [34], Spall [36], Andradottir [37], Rubinstein and Melamed [38], Pflug [39], Rubinstein and Shapiro [16], as well as other chapters in the Elsevier Handbook on Simulation edited by Henderson and Nelson [40].

Finally, a useful source for following the state-of-the-art research developments in stochastic gradient estimation and simulation optimization are the annual Proceedings of the Winter Simulation Conference, available on-line at <http://www.wintersim.org>.

Brief Historical Notes

PA was “invented” by Ho *et al.* [41], when the first author was consulting on a real-world buffer design problem for a Fiat Motor Company serial production line. The LR/SF method was introduced by Glynn [42], Reiman and Weiss [43], and Rubinstein [44]. The first application of PA to inventory systems was by Fu [35] for (s,S) policies, where both IPA and SPA estimators are derived. Glasserman and Tayur [45] treat the easier base-stock setting where IPA is applicable. The first applications of stochastic gradient estimation to finance are contained in Fu and Hu [46] and Broadie and Glasserman [47].

STOCHASTIC HAZARD PROCESS

SÜLEYMAN ÖZEKİCİ
Department of Industrial
Engineering, Koç University,
Istanbul, Turkey

The reliability of a device or system is represented by the survival probability

$$R(t) = P\{L > t\} = e^{-H(t)} \quad (1)$$

for $t \geq 0$ where L is the lifetime and H is the hazard function. This may also be rewritten as

$$H(t) = -\ln R(t) \quad (2)$$

and the hazard function is increasing in $t \geq 0$. Moreover, if it is absolutely continuous and the hazard rate function $h(t) = dH(t)/dt$ exists almost everywhere, then the hazard at time t is $H(t) = \int_0^t h(s)ds$.

In reliability theory, perhaps the most widely used model to represent the lifetime is the first passage time,

$$L = T_S = \inf \{t \geq 0; X_t \geq S\} \quad (3)$$

when a wear process $X = \{X_t; t \geq 0\}$ exceeds a critical threshold $S \geq 0$. This implies that the item fails as soon as the total wear X exceeds the critical level S . The probabilistic structure of failure is then embedded in the stochastic structure of the wear process X and the threshold S . The literature is full of a variety of models with continuous wear and discontinuous shocks as they occur randomly in time. We refer the reader to Abdel-Hameed *et al.* [1] and Aven and Jensen [2] for examples.

In this article, we focus on the hazard function and process. Our terminology will call H the hazard function when it is deterministic, and hazard process when it is stochastic. To make this distinction clear, we use the notation $H(t)$ and H_t to denote the deterministic and stochastic hazard accumulated until time

t , respectively. Needless to say, as implied by the title, the discussion is on the stochastic case for the most part. However, we first take a look at some of the implications behind the simple deterministic representation (1) in the section titled “The Hazard Function”. The section titled “The Hazard Process” discusses some stochastic representations for H , the next section discusses briefly “Modulation via Random Environments”, and we take a more detailed look at Markov modulated models in the section titled “Intrinsic Aging Models” after a brief discussion on modulation via random environments in the third section. Finally, this article is intended to provide the reader a clear and useful understanding and interpretation of the hazard function and process. Technical details and proofs are omitted and we will try to keep the theoretical derivations at the minimal level. In our notation, we let $\mathbb{R}_+ = [0, +\infty)$ and $\mathbb{R}_0 = (0, +\infty)$ denote the set of nonnegative and positive real numbers, respectively.

THE HAZARD FUNCTION

We now consider some models where the hazard function H has meaningful interpretations. An interesting characterization of the lifetime distribution implied by (1) is that

$$P\{L > t\} = e^{-H(t)} = P\{\hat{L} > H(t)\}, \quad (4)$$

where $\hat{L}$ is a random variable that has the exponential distribution with rate 1. In view of the passage time representation (3), we can also write $L = T_{\hat{L}}$ as the passage time of the deterministic function $X_t = H(t)$ when the threshold $S = \hat{L}$ is exponentially distributed with rate 1. One can therefore think of the increasing process H as an “intrinsic” aging process such that the system fails as soon as its intrinsic age exceeds its intrinsic lifetime $\hat{L}$. This observation allowed Çınlar and Özekici [3] to measure the age of complex systems by an intrinsic clock given by the hazard

function so that the intrinsic lifetime is simply exponentially distributed. This implies that any system is initially endowed by an exponentially distributed lifetime with rate 1 and it fails when its intrinsic age, or hazard, exceeds this threshold. Singpurwalla [4], in a recent closely related article, calls this endowment the hazard potential that the system consumes by time and it fails once it is depleted. Most of the stochastic hazard models that we consider later in this article will be extensions of this idea where intrinsic aging depends on some random environmental process that affects the deterioration or failure properties of the system. This provides an intuitive and natural construction of stochastic hazard processes.

The structure in (1) also holds in shock models where the system is subject to shocks at times $\{U_i\}$ with random magnitudes $\{Y_i\}$ such that the pairs $\{(U_i, Y_i)\}$ form a Poisson random measure M on $\mathbb{R}_+ \times \mathbb{R}_0$ with some mean measure $m(dt, dy) = \lambda(t)dtF(dy)$, where λ is the shock arrival rate function and F is the distribution function of the shock magnitudes. If the system fails as soon as the magnitude of a shock at time $t \geq 0$ exceeds a critical threshold $a(t) \geq 0$, then

$$\begin{aligned} P\{L > t\} &= P\{M\{(u, y); 0 \leq u \leq t, y > a(t)\} = 0\} \\ &= e^{-H(t)}, \end{aligned} \quad (5)$$

where

$$\begin{aligned} H(t) &= m\{(u, y); 0 \leq u \leq t, y > a(t)\} \\ &= \int_0^t \lambda(u) du \int_{a(u)}^{+\infty} F(dy) \\ &= \int_0^t \lambda(u)(1 - F(a(u))) du, \end{aligned} \quad (6)$$

and the hazard rate function becomes $h(t) = dH(t)/dt = \lambda(t)(1 - F(a(t)))$. The deterministic function a depicts the shock tolerance of the item and it will decrease in time if the item gets less tolerant to shocks as it ages. A shock with the same magnitude at a later time is then more likely to cause failure.

A special case of (6) is when the threshold level is $a = 0$ and $Y_i = 1$ trivially so that $L = U_1$ and the system fails at the time of the

first shock. This gives

$$H(t) = \int_0^t \lambda(u) du \quad (7)$$

by (6). Now, the stochastic process

$$N_t = \int_0^t \int_{\mathbb{R}_0} y M(du, dy) = \sum_{U_i \leq t} Y_i = \sum_i I_{\{U_i \leq t\}} \quad (8)$$

is a nonstationary Poisson process with mean function $H(t) = \int_0^t \int_{\mathbb{R}_0} y m(du, dy) = \int_0^t \lambda(u) du$ and L is the time of first arrival of N . This provides a very simple interpretation of the hazard function H since the hazard rate $h(t) = dH(t)/dt = \lambda(t)$ is simply the arrival rate of the nonstationary Poisson process at any time t . One can therefore think of the failure time as the time of the first arrival of a nonstationary Poisson process with expectation function given by the hazard function.

THE HAZARD PROCESS

The hazard functions discussed in the previous section are implicitly assumed to be deterministic. In this article, we focus on an interesting extension of this idea that has attracted a lot of attention by supposing that $H = \{H_t; t \geq 0\}$ is indeed an increasing stochastic process taking values in $\mathbb{R}_+$. We provided two interpretations of the hazard function as an intrinsic aging process by (4), and as an arrival expectation function by (7). A natural extension is to randomize them via modulation by an external stochastic process. We focus on this issue later in more detail in the third and fourth sections. The concept of random hazard functions is also used in earlier papers by Gaver [5] and Arjas [6]. The intrinsic aging model of Çinlar and Özekici [3] is another example where the stochastic hazard process is modulated by an external environmental process that describes the conditions under which the system operates. Lindley and Singpurwalla [7] discuss the effects of the random environment on the reliability of a system consisting of components which share the same environment. Although the initial state

of the environment is random, they assume that it remains constant in time and components have exponential life distributions in each possible environment. Kebir [8] models the hazard rate as a stochastic process with independent increments. In case the hazard rate process is increasing, this leads to an explicit computational formula for the reliability function using its Itô decomposition. In a recent article, Singpurwalla [4] introduces a novel approach to model lifetime distribution through the hazard potential. Stochastic hazard functions are also used in different contexts that do not necessarily involve devices. For example, Ludkovski and Young [9] suppose that the hazard or mortality rate of an individual's lifetime is given by a diffusion process in their financial model on the pricing of mortality contingent claims. Cathcart and Al-Jahel [10] use a doubly stochastic hazard rate process for the default time of bonds where the primary objective is to price them.

The stochastic hazard process H is an increasing right-continuous process and Çinlar [11] gives an excellent description of such processes with Markov and semi-Markov structures. Although his discussions are on the stochastic structure of wear processes, the results also apply to our hazard process. For example, if H is continuous and strong Markov, then it must be deterministic and this case indeed corresponds to a deterministic hazard function discussed in the first section for which (4) holds. An interesting model of sufficient generality for our purposes is when H is a right-continuous strong Markov process that is also quasi-left-continuous. Then, we have the stochastic representation

$$H_t = H_0 + \int_0^t b(H_u) du + \int_{[0,t] \times \mathbb{R}_0} k(H_{u-}, y) M(du, dy), \quad (9)$$

where $b: \mathbb{R}_+ \rightarrow \mathbb{R}_+$, $k: \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ are deterministic functions and M is a Poisson random measure with some mean measure $m(du, dy) = duv(dy)$ for some σ -finite, diffuse measure v on $\mathbb{R}_+$. The structure is slightly more complicated since the actual hazard process is obtained from a process

that satisfies (9) after a random time change. But, we think that the model in (9) is of sufficient interest, generality, and computational tractability. In fact, the infinitesimal generator

$$Gf(x) = \lim_{t \downarrow 0} \left(\frac{E[f(H_t) - f(H_0) | H_0 = x]}{t} \right) \quad (10)$$

of the Markov process H is given by

$$Gf(x) = f'(x)b(x) + \int_{\mathbb{R}_0} [f(x+k(x,y)) - f(x)] v(dy) \quad (11)$$

for bounded and differentiable functions $f: \mathbb{R}_+ \rightarrow \mathbb{R}$ with derivative $f'(x) = df(x)/dx$. If the points of the Poisson random measure M are labeled as $\{(U_i, Y_i)\}$, we can also write

$$H_t = H_0 + \int_0^t b(H_u) du + \sum_{U_i \leq t} k(H_{U_i-}, Y_i) \quad (12)$$

in a simplified format. Here, $b(H_u)$ is the continuous rate of increase in the hazard depending on the hazard level H_u at any time u . Moreover, a shock occurring at time U_i with magnitude Y_i increases the hazard by an amount $k(H_{U_i-}, Y_i)$ depending on the hazard level H_{U_i-} just before the shock time U_i and the shock magnitude Y_i .

When the hazard process is stochastic, we can express the reliability function as

$$R(t) = P\{\hat{L} > H_t\} = E\left[E\left[\hat{L} > H_t | H_t\right]\right] = E\left[e^{-H_t}\right], \quad (13)$$

in view of (4) by supposing that the intrinsic lifetime $\hat{L}$ is independent of the hazard process H . In other words, the system fails as soon as the hazard process exceeds an exponential threshold with rate 1.

For the increasing Markov process H in (9), we can use potential theory and the generator (11) to write

$$E[f(H_t) | H_0 = x] = f(x) + \int_0^t E[Gf(H_s) | H_0 = x] ds. \quad (14)$$

In particular, when $f(x) = e^{-x}$, we trivially have $f'(x) = -e^{-x} = -f(x)$ and (14) becomes

$$\begin{aligned} E[e^{-H_t} | H_0 = x] \\ = e^{-x} - \int_0^t E[e^{-H_s} c(H_s) | H_0 = x] ds, \end{aligned} \quad (15)$$

where $c(x) = b(x) + \int_{\mathbb{R}_0} [1 - e^{-k(x,y)}] v(dy)$. Therefore, given any initial hazard $H_0 = x$, the reliability function $R(t) = E[e^{-H_t} | H_0 = x]$ satisfies the differential equation

$$\frac{dE[e^{-H_t} | H_0 = x]}{dt} = -E[e^{-H_t} c(H_t) | H_0 = x] \quad (16)$$

with the boundary condition $R(0) = E[e^{-H_0} | H_0 = x] = e^{-x}$. One has to solve (16) in order to determine the reliability function corresponding to the stochastic hazard process given by (9). As a special case, if $b(x) = b$, and $k(x, y) = k(y)$ independent of x , then $c(x) = b + \int_{\mathbb{R}_0} [1 - e^{-k(y)}] v(dy) = c$ independent of x . Therefore, (16) clearly implies that $dR(t)/dt = -cR(t)$ and this leads to the exponential distribution since the solution is $R(t) = R(0)e^{-ct}$.

A reasonable example for stochastic hazard processes is an increasing Lévy process which is basically a process that has independent and stationary increments. This is a very useful process in modeling stochastic phenomena occurring in many fields of sciences and engineering. Various properties and applications of Lévy processes are discussed in Barndorff-Nielsen *et al.* [12]. Gjessing *et al.* [13] use stochastic hazard processes based on Lévy processes and discuss applications in biological sciences. An increasing Lévy process has the representation

$$H_t = bt + \int_{[0,t] \times \mathbb{R}_0} yM(du, dy) \quad (17)$$

with $b \geq 0$, where M is a Poisson random measure on $\mathbb{R}_+ \times \mathbb{R}_0$ with mean measure $m(du, dy) = duv(dy)$ for some Lévy measure v that satisfies $\int_{\mathbb{R}_0} \min\{1, y\}v(dy) < +\infty$. This is clearly a special case of the general Markov model in (9) obtained by taking

$b(x) = b, k(x, y) = y$ independent of x , and setting $H_0 = 0$. The structure in (17) implies that the expected hazard is

$$\begin{aligned} E[H_t] &= bt + \int_{[0,t] \times \mathbb{R}_0} ym(du, dy) \\ &= \left(b + \left(\int_{\mathbb{R}_0} yv(dy) \right) \right) t \end{aligned} \quad (18)$$

and reliability becomes

$$R(t) = E[e^{-H_t}] = e^{-\left(b + \left(\int_{\mathbb{R}_0} yv(dy)(1 - e^{-y})\right)\right)t} = e^{-ct}, \quad (19)$$

where $c = b + \int_{\mathbb{R}_0} (1 - e^{-y}) v(dy)$. Note that (19) corresponds to the exponential distribution with hazard rate c . It is also clear that (19) satisfies (16) since $c(x) = c$ independent of x .

Among the increasing Lévy processes, there are three that are worth mentioning at this time. They all lead to the exponential distribution with different hazard rates through different stochastic hazard processes. The first one is the compound Poisson process when $v(dy) = \lambda F(dy)$ where λ is the arrival rate and F is the distribution of the jumps. In this case, the number of jumps of the hazard process H during any interval is finite and

$$P\{H_t \leq x + bt\} = \sum_{n=0}^{+\infty} \frac{e^{-\lambda t} (\lambda t)^n}{n!} F^{*n}(x), \quad (20)$$

where F^{*n} is the n -fold convolution of F . Moreover,

$$E[H_t] = (b + \lambda E[Y]) t, \quad (21)$$

where Y is a generic random variable that represents the jump magnitude of the compound Poisson process with distribution F . The hazard rate is

$$\begin{aligned} c &= b + \lambda \int_0^{+\infty} F(dy) (1 - e^{-y}) \\ &= b + \lambda E[1 - e^{-Y}]. \end{aligned} \quad (22)$$

The second one is the gamma process when $v(dy) = (\beta e^{-\alpha y}/y) dy$ where $\alpha > 0$ is the scale

parameter and $\beta > 0$ is the shape parameter. This leads to a process H that has an infinite number of jumps in any finite interval with the gamma distribution

$$P\{H_t \leq x + bt\} = \int_0^x \left(\frac{\alpha e^{-\alpha y} (\alpha y)^{\beta t - 1}}{\Gamma(\beta t)} \right) dy \quad (23)$$

and finite expectation

$$E[H_t] = (b + (\beta/\alpha))t. \quad (24)$$

The corresponding hazard rate is

$$\begin{aligned} c &= b + \int_0^{+\infty} \left(\frac{\beta e^{-\alpha y}}{y} \right) (1 - e^{-y}) dy \\ &= b + \beta \ln(1 + (1/\alpha)). \end{aligned} \quad (25)$$

Dykstra and Laud [14] proposed an extension of the gamma process to represent the hazard rate process. This representation leads to some desirable properties in terms of Bayesian analysis of reliability models. Gamma processes have been used widely to model random phenomena in many fields. In an earlier work by Moran [15] on storage models, for example, the random flow of water in dams is depicted by a gamma process.

Finally, we have a stable process when $v(dy) = (\alpha\beta y^{-(1+\beta)} / \Gamma(1-\beta)) dy$ where $\alpha > 0$ is the scale parameter and $0 < \beta < 1$ is the shape index. Here, $\Gamma(z) = \int_0^{+\infty} s^{z-1} e^{-s} ds$ is the gamma function. The stable process H also has an infinite number of jumps in any finite interval, but H_t is finite almost surely with the Laplace transform

$$E[e^{-\gamma H_t}] = e^{-(b + \alpha\gamma^\beta)t} \quad (26)$$

and infinite expectation $E[H_t] = +\infty$. The hazard rate now becomes

$$c = b + \int_0^{+\infty} \left(\frac{\alpha\beta y^{-(1+\beta)}}{\Gamma(1-\beta)} \right) (1 - e^{-y}) dy = b + \alpha. \quad (27)$$

Stochastic hazard processes can also be constructed using continuous stochastic processes. However, not all of them are suitable candidates. The increasing Lévy process

in (17), for example, reduces to the deterministic hazard function $H(t) = bt$ when the sample path is restricted to be continuous. A continuous Lévy process, on the other hand, is a Brownian motion which does not have increasing sample paths. We can obtain another stochastic hazard processes through the maximum process

$$H_t = \max_{0 \leq u \leq t} W_u, \quad (28)$$

where W is the standard Brownian motion, or the Wiener process. It is well known that

$$\begin{aligned} P\{H_t \leq x\} &= 1 - 2P\{W_t > x\} \\ &= 1 - 2 \int_{x/\sqrt{t}}^{+\infty} \frac{1}{\sqrt{2\pi}} e^{-u^2/2} du \end{aligned} \quad (29)$$

since W_t has the normal distribution with mean 0 and variance t . This distribution implies that the reliability function is

$$\begin{aligned} R(t) &= E[e^{-H_t}] = \int_0^{+\infty} e^{-x} P\{H_t \in dx\} \\ &= \int_0^{+\infty} e^{-x} \left(\frac{2e^{-x^2/2t}}{\sqrt{2\pi t}} \right) dx = 2e^{t/2} \Phi(-\sqrt{t}), \end{aligned} \quad (30)$$

where Φ is the standard normal distribution function. Another increasing process is obtained by the inverse

$$\mathcal{H}_t = \inf\{s \geq 0 : H_s > t\}. \quad (31)$$

This is, in fact, a special case that is already covered in our previous discussion on Lévy processes since it is well known that the process $\mathcal{H}$ in (28) is also a Lévy, in fact stable, process with scale parameter $\alpha = \sqrt{2}$ and shape index $\beta = 0.5$ so that $v(dy) = (1/\sqrt{2\pi y^3}) dy$.

A suitable candidate for the hazard process is an increasing Markov process. For computational tractability, if the Markov process H is defined on some finite state space $E \subseteq \mathbb{R}_+$, then using uniformization results under reasonable assumptions we have the representation

$$H_t = X_{N_t}, \quad (32)$$

where $X = \{X_n; n = 0, 1, \dots\}$ is an increasing Markov chain with an upper triangular transition matrix P , and $N = \{N_t; t \geq 0\}$ is a Poisson process with some rate λ . Now,

$$P\{H_t = j | H_0 = i\} = \sum_{n=0}^{+\infty} \frac{e^{-\lambda t} (\lambda t)^n}{n!} P^n(i, j) \quad (33)$$

and the reliability function is

$$\begin{aligned} R(i, t) &= E \left[e^{-H_t} | H_0 = i \right] \\ &= e^{-\lambda t} \sum_{j \in E} e^{-j} \sum_{n=0}^{+\infty} \frac{(\lambda t)^n}{n!} P^n(i, j) \\ &= e^{-\lambda t} \sum_{j \in E} e^{-j} e^{\lambda t P}(i, j) \end{aligned} \quad (34)$$

conditional on the initial hazard $H_0 = i$. In (34), $e^{\lambda t P}$ is the exponential matrix

$$e^{\lambda t P} = \sum_{n=0}^{+\infty} \frac{s^n}{n!} A^n = \lim_{n \rightarrow +\infty} \left(I + \frac{sA}{n} \right)^n \quad (35)$$

defined for any matrix A and scalar $s \geq 0$. The computation of the matrix exponential (35) can be done in many ways and we refer the interested reader to Moler and Loan [16] for various methods. MATLAB, for example, uses the scaling and squaring method employing Padé approximants.

Another approach to model the stochastic hazard process H is through its stochastic hazard rate process $h_t = dH_t/dt$. An interesting model in finance is used by Ludkovsky and Young [9] where the stochastic hazard is given by the nonnegative diffusion

$$dh_t = \mu(h_t, t)h_t dt + \sigma(t)h_t dW_t, \quad (36)$$

where μ and σ are the drift and volatility terms respectively while W is the Wiener process. The hazard rate is for the lifetimes of individuals or insurers on which mortality contingent claims or derivatives are written. Clearly, stochastic calculus is used to analyze issues related to the pricing of such financial instruments where the risk is realized when mortality happens at the lifetime of the individual before maturity.

MODULATION VIA RANDOM ENVIRONMENTS

Most of the complex stochastic models in operations research and management sciences operate in randomly changing environments. Stochastic and deterministic model parameters are often modulated by this random environment. This is quite evident in reliability applications where deterioration and aging happens intrinsically depending on the state of the environment. However, the idea has far more general applicability in a variety of problems and we will provide a brief discussion in this section before we focus on reliability applications in more detail. We use the term “environment” in a generic sense so that it represents any set of conditions that affect the stochastic structure of the model investigated. The concept of an “environmental” process, in one form or another, has been used in the literature for various purposes. Neveu [17] provides an early reference to paired stochastic processes where the first component is a Markov process while the second one has conditionally independent increments given the first. Ezhov and Skorohod [18] refer to this as a Markov process with homogeneous second component. In a more modern setting, Çınlar [19] introduced Markov additive processes and provided a detailed description on the structure of the additive component. The environment is modeled as a Markov process in all these cases and the additive process represents the stochastic evolution of a quantity of interest.

In reliability models, a complex device generally consists of a large number of components with stochastically dependent lifetimes. In the literature, random environments are used to provide a tractable model of stochastic dependence among the components where the environment is an external process that depicts all physical, structural, operational, and other conditions which affect the deterioration, aging, and failure of the components. Since all components are subjected to the same environmental conditions, their lifetimes are dependent via their common environment. Thus, the environmental process is actually a factor of variation in the

failure structure of the components. These ideas were introduced by Çınlar and Özekici [3] who propose to construct an intrinsic clock which ticks differently in different environments to measure the intrinsic age of the device. The environment is modeled by a semi-Markov jump process and the intrinsic age is represented by the cumulative hazard accumulated in time during the operation of the device in the randomly varying environment. This is a rather stylish choice which envisions that the intrinsic lifetime of any device has an exponential distribution with parameter 1. The intrinsic aging model of Çınlar and Özekici [3] is studied further by Çınlar *et al.* [20] to determine the conditions that lead to associated component lifetimes. The association of the lifetimes of components subjected to a randomly varying environment is discussed by Lefèvre and Milhaud [21]. In a recent article, Singpurwalla [4] provides a review by discussing hazard potentials in reliability modeling.

Random environments are also used in analyzing mission-based or phased-mission systems. In this setting, a device is designed to perform missions consisting of a possibly random sequence of phases with random durations. The environmental process is now the mission process and the failure rate depend on the phase of the mission performed at any time. Most of the literature on phased-mission systems assume that the sequence of the phases are deterministic, and that the durations are either deterministic or exponentially distributed. The main reason is that random durations and sequences make the analysis more complex. There are only a few papers which consider dynamic phase sequences that are modified according to the states of the system. Deterministic phase durations may be realistic for some applications such as aerospace applications, discussed by Mura and Bondavalli [22] where phases are preplanned on the ground. However, Alam and Al-Saggaf [23] state that random phase durations are more realistic in many systems such as real-time control for aircraft and space vehicles in which different sets of computational tasks are executed during different phases of a control process.

Since the exponential distribution is not suitable to model all phase durations due to its long tail behavior, as stated by Mura *et al.* [24], phase durations should be modeled by general random variables. The main concern is the computation of the reliability function. However, there may be several definitions of reliability in these systems depending on the objectives of the mission. The classical definition, of course, is one of *system reliability* which is the probability that the system will function without failure for a given amount of time. Other definitions focus on the phases of the mission as well as the whole of the mission. *Mission reliability* is the probability that a given number of phases or the whole mission will be completed without system failure. Finally, *phase reliability* will refer to the probability that a given critical phase of the mission will be completed without failure by a given time. We refer the reader to Çekyay and Özekici [25,26] for the reliability of semi-Markov and Markov missions with different component failure structures.

There is also an enormous amount of literature on so-called condition-based reliability systems where the condition of the system is observed first before a decision is made on maintenance. Here, the condition of the system is often represented by some stochastic process of an endogenous nature. In other words, the condition is not depicted by some external environmental process, but it is a process that reflects the condition of the system and the time to failure depends on the current condition. The modulation of the reliability model is therefore done by this process. Chen and Trivedi [27] consider the optimal conditional-maintenance problem using semi-Markov decision processes, while Wang *et al.* [28] provide a recent work on condition-based replacement problem with spare parts provisioning. An extended discussion and survey on condition-based maintenance models can be found in Çekyay and Özekici [29].

A similar modulation holds in software reliability systems as well. In this case, the way that the user operates the system, or the so-called operational profile, plays a key role in software reliability assessment. Failure

probabilities of the modules and system reliability, all depend on the random sequence of operations it performs. Musa [30] defines the operational profile of any software as the set of all operations that it is designed to perform with a probability distribution defined on them. The operational profile in this setting provides the random environment for the software system. This approach is used in Özekici and Soyer [31] to analyze probabilistic and statistical issues related to software reliability.

Özekici [32] discusses the use of random environments in complex models in operations research with applications in reliability, inventory, and queueing. In inventory models, the stochastic structure is depicted by the demand and the lead-time processes. Song and Zipkin [33] argue that the demand for the product may be affected by a randomly changing “state-of-the-world,” which we choose to call the “environment” in our exposition. A periodic review model in a random environment with uncertain supply is analyzed in Özekici and Parlar [34]. Erdem and Özekici [35] consider inventory models with a demand process that fluctuates with respect to stochastically changing economic conditions. Queueing models also involve stochastic and deterministic parameters that are subject to variations depending on some environmental factors. The customer arrival rate as well as the service rate are not necessarily constants that remain intact throughout the entire operation of the queueing system. A comprehensive discussion on Markov modulated queueing systems can be found in Prabhu and Zhu [36] where customer arrival and service rates are modulated by a Markov process. More recently, Çanakoğlu and Özekici [37] and Çelikyurt and Özekici [38] applied the idea to various portfolio optimization problems where the correlation among returns of risky assets is formulated by a stochastic market representing the underlying financial, economic, social, and other factors. In the valuation model of Cathcart and Al-Jahel [10] for defaultable bonds, the time to default has a hazard rate that depends on a latent state variable and stochastic interest rate. Interested readers

are referred to Rolski *et al.* [39] for further applications in queueing, insurance, and finance.

INTRINSIC AGING MODELS

Although the discussions in the previous section clearly illustrate the use of random environments in operations research and management sciences, the concept offers more applicability in reliability and maintenance models. It is generally assumed that a device always works in a given fixed environment. The probability law of the deterioration and failure process thus remains intact throughout its useful life. The life distribution and the corresponding failure rate function is taken to be the one obtained through statistical life testing procedures that are usually conducted under ideal laboratory conditions by the manufacturer of the device. Data on lifetimes may also be collected while the device is in operation to estimate the life distribution. In any case, the basic assumption is that the prevailing environmental conditions either do not change in time or, in case they do, they have no effect on the deterioration and failure of the device. Therefore, statistical procedures in estimating the life distribution parameters, and decisions related with replacement and repair are based on the calendar age of the item.

There has been growing interest in recent years in reliability and maintenance models where the main emphasis is placed on the so-called intrinsic age of a device rather than its real age. This is necessitated by the fact that devices often work in varying environments during which they are subject to varying environmental conditions with significant effects on performance. The deterioration and failure process therefore depends on the environment, and it no longer makes much sense to measure the age in real time without taking into consideration the different environments that the device has operated in. There are many examples where this important factor cannot be neglected or overlooked. Consider, for example, the jet engine of

an airplane which is subject to varying atmospheric conditions such as pressure, temperature, humidity, and mechanical vibrations during take-off, cruising, and landing. The changes in these conditions cause the engine to deteriorate, or age, according to a set of rules which may well deviate substantially from the usual one that measures the age in real time irrespective of the environment.

As a matter of fact, the intrinsic age concept is being used routinely in practice in one form or another. In aviation, the calendar age of an airplane since the time it was actually manufactured is not of primary importance in determining maintenance policies. Rather, the number of take-offs and landings, total time spent cruising in fair conditions or turbulence, or total miles flown since manufacturing or since the last major overhaul are more important factors. Another example is a machine or a workstation in a manufacturing system which may be subject to varying loading patterns depending on the production schedule. In this case, the atmospheric conditions do not necessarily change too much in time, and the environment is now represented by varying loading patterns so that, for example, the workstation ages faster when it is overloaded, slower when it is underloaded, and not at all when it is not loaded or kept idle. Therefore, the term *environment* is used in a loose sense here so that it represents any set of conditions that affect the deterioration and aging of the device.

Reliability models in random environments provide a perfect opportunity in order to model stochastic hazard processes. This is because the failure rate at any time is random since the state of the environment that determines it is random. Intrinsic aging in Çinlar and Özekici [3] is described by the simple relationship

$$\frac{dH_t}{dt} = r(Y_t, H_t), \quad (37)$$

where H_t is the intrinsic age or hazard of the system at time t and $Y = \{Y_t; t \geq 0\}$ is an environmental process with state space E that reflects the states of various environmental factors and r is the hazard rate

function. Clearly, $r(i, a)$ is the hazard rate when the hazard is a in environment i .

Intrinsic Aging in a Fixed Environment

Suppose, for now, that the environment remains fixed at some state i so that $Y_t = i$ for all $t \geq 0$. During any environment i , the reliability function

$$R(i, t) = P\{L > t | Y = i\} = e^{-H(i, t)} \quad (38)$$

is known, where $H(i, t)$ is the corresponding deterministic hazard function. Now, (38) allows us to construct an intrinsic clock to measure the intrinsic age of the device at time t as $H_t = H(i, t)$ and the real lifetime is characterized by

$$L = \inf\{s \geq 0; H_s \geq \hat{L}\}, \quad (39)$$

where $\hat{L}$ is a random variable representing the intrinsic lifetime. Moreover, it has an exponential distribution with parameter 1 since

$$P\{L > t | Y = i\} = P\{\hat{L} > H_t | Y = i\} = e^{-H_t}. \quad (40)$$

The intrinsic age at time t is defined as $H_t = H(i, t)$ provided that the environment is in state i throughout $[0, t]$. Then,

$$\tau(i, a) = \inf\{t \geq 0 : H(i, t) > a\} \quad (41)$$

is the amount of operation time it takes to age a brand new item to intrinsic age a in environment i . We now define

$$h(i, a, t) = H(i, \tau(i, a) + t) \quad (42)$$

so that this gives the intrinsic age at time t in state i given that the intrinsic age is a at the beginning. As long as the environment is fixed, aging occurs deterministically according to $h(i, a, t)$ and the item fails as soon as the age exceeds the exponential threshold.

Intrinsic Aging in a Random Environment

Suppose now that the environmental process is not fixed but described as the minimal semi-Markov process associated with a Markov renewal process. Let T_n denote the time of the n th environment change and X_n denote the n th environmental state for $n \geq 0$ with $T_0 \equiv 0$. The main assumption is that the process $(X, T) = \{(X_n, T_n); n \geq 0\}$ is a Markov renewal process on the state space $E \times \mathbb{R}_+$ with some semi-Markov kernel Q . Moreover, $Y = \{Y_t; t \geq 0\}$ is the minimal semi-Markov process associated with (X, T) . More precisely, $Y_t = X_n$ whenever $T_n \leq t < T_{n+1}$. For any $i, j \in E$ and $t \geq 0$,

$$Q(i, j, t) = P[X_{n+1} = j, T_{n+1} - T_n \leq t | X_n = i] \quad (43)$$

and it is well known that X is a Markov chain on E with transition matrix $P(i, j) = P[X_{n+1} = j | X_n = i] = Q(i, j, +\infty)$. We further suppose for technical reasons that the Markov renewal process has infinite lifetime so that $\sup_n T_n = +\infty$. Note that if the state space E is finite, this condition is always satisfied and the assumption is required only when E is infinite. We refer the reader to Çinlar [40] for a more rigorous and detailed treatment of Markov renewal processes and theory. The probabilistic structure of T is given by the conditional distributions

$$P\{T_{n+1} - T_n \leq t | X_n = i, X_{n+1} = j\} = \frac{Q(i, j, t)}{P(i, j)} \quad (44)$$

for $P(i, j) > 0$. Moreover, it is easy to see that

$$G_i(t) = P\{T_1 \leq t | X_0 = i\} = \sum_{j \in E} Q(i, j, t) \quad (45)$$

denotes the distribution of the duration of phase i . We let $\bar{G}_i = 1 - G_i$ denote the corresponding survival function for each state i .

An intuitive choice to extend the construction of the intrinsic aging process in this setting is to measure the age by the hazard that accumulates during the operation of the device in the randomly varying environment. If the environment is not fixed, then

the intrinsic aging process $H = \{H_t; t \geq 0\}$ of the item is a continuously increasing stochastic hazard process constructed recursively by

$$H_{T_n+t} = h(X_n, H_{T_n}, t) = H(X_n, \tau(X_n, H_{T_n}) + t) \quad (46)$$

provided that $t \leq T_{n+1} - T_n$ and the item is functioning at time $T_n + t$.

This intrinsic aging model simply combines the hazard functions of the components in the environmental states. Given the deterministic hazard functions $\{h(i, \cdot); i \in E\}$ and a realization of the environmental process Y , the age process H is completely defined by (46) recursively by taking $n = 0, 1, 2, \dots$. If the initial age is $H_0 = a$ and the initial environment is $X_0 = i$ with $T_0 \equiv 0$, then the initial real age of the component is $\tau(i, a)$ and it ages deterministically as $H_s = h(i, a, s)$ for $s \leq T_1$. At some time $T_1 = u$, the environment jumps to state $j \in E$ with some probability $Q(i, j, du)$ and the age is now the hazard given by $H_{u+s} = h(j, H_u, s)$ for $u + s \leq T_2$. The sample path of H is constructed similarly in time as the environmental process evolves so that, in general, if the environment jumps to some state $k \in E$ at the n th jump time $T_n = t$, then the age evolves as $H_{t+s} = H(k, H_t, s)$ so long as $t + s \leq T_{n+1}$.

To simplify our notation, we use $P_{ia}(D) = P(D | X_0 = i, H_0 = a, \hat{L} > a)$ and $E_{ia}[Z] = E[Z | X_0 = i, H_0 = a, \hat{L} > a]$ to denote conditional probabilities and expectations for any event D and random variable Z , respectively. The construction of the stochastic hazard process allows us to write the reliability function as

$$\begin{aligned} R(i, a, t) &= P_{ia}\{L > t\} = P_{ia}\{\hat{L} > H_t\} \\ &= E_{ia}\left[e^{-(H_t - a)}\right] \end{aligned} \quad (47)$$

since the intrinsic lifetime has the exponential distribution with rate 1. The computation of (47), however, is not a simple task in general. In case $T_1 > t$ is given, then the conditional probability is simply

$$P_{ia}\{L > t | T_1 > t\} = e^{-(h(i, a, t) - a)} \quad (48)$$

trivially since $H_t = h(i, a, t)$ whenever $X_0 = i$, $H_0 = a$, and $T_1 > t$. We now consider some interesting cases in decreasing order of complexity and generality.

General Model in a Semi-Markov Environment

We can determine the reliability of the item using a Markov renewal argument for the system reliability function $f(i, a, t) = P_{ia}\{L > t\}$. By conditioning, we can write

$$\begin{aligned} f(i, a, t) &= P_{ia}\{L > t, T_1 > t\} + P_{ia}\{L > t, T_1 \leq t\} \\ &= \bar{G}_i(t) e^{-(h(i, a, t) - a)} + \sum_{j \in E} \int_{[0, t]} Q(i, j, ds) \\ &\quad \times e^{-(h(i, a, s) - a)} f(j, h(i, a, s), t - s) \\ &= \bar{G}_i(t) e^{-(h(i, a, t) - a)} \\ &\quad + \sum_{j \in E} \int_{\mathbb{R}_+ \times [0, t]} \tilde{Q}(i, a; j, db; ds) f(j, b, t - s), \end{aligned} \quad (49)$$

where $\tilde{Q}$ is a semi-Markov kernel on $E \times \mathbb{R}_+$ defined by

$$\tilde{Q}(i, a; j, B; ds) = Q(i, j, ds) 1_B(h(i, a, s)) \quad (50)$$

for all $i, j \in E, a \in \mathbb{R}_+, B \subseteq \mathbb{R}_+$, and $s \geq 0$. Here, $1_B(a)$ is the indicator function in $a \in \mathbb{R}_+$ which is equal to 1, if and only if $a \in B$. Moreover, it is obviously a measure in $B \subseteq \mathbb{R}_+$. The first part of (49) follows from (45) and (48). Thus, (49) is a Markov renewal equation $f = g + \tilde{Q} * f$ where $g(i, a, t) = \bar{G}_i(t) e^{-(h(i, a, t) - a)}$, and it has a unique solution $f = \tilde{R} * g$ so that the reliability function is

$$\begin{aligned} R(i, a, t) &= P_{ia}\{L > t\} \\ &= \sum_{j \in E} \int_{\mathbb{R}_+ \times [0, t]} \tilde{R}(i, a; j, db; ds) \bar{G}_j(t - s) \\ &\quad \times e^{-(h(j, b, t - s) - b)}, \end{aligned} \quad (51)$$

where $\tilde{R} = \sum_{n=0}^{+\infty} \tilde{Q}^n$ is the Markov renewal kernel corresponding to $\tilde{Q}$.

Exponential Model in a Semi-Markov Environment

A special case with some simplification is when the aging in each state happens at a constant rate so that the item fails exponentially. If the hazard rate in state i is λ_i , then $h(i, a, t) = a + \lambda_i t$ and $e^{-(h(i, a, t) - a)} = e^{-\lambda_i t}$ independent of the initial age a . For $f(i, t) = P_i\{L > t\}$, the Markov renewal (49) now simplifies to

$$f(i, t) = \bar{G}_i(t) e^{-\lambda_i t} + \sum_{j \in E} \int_{[0, t]} \tilde{Q}(i, j, ds) f(j, t - s), \quad (52)$$

where $\tilde{Q}(i, j, ds) = Q(i, j, ds) e^{-\lambda_i s}$. The solution of (52) has a simpler structure which gives the reliability function

$$\begin{aligned} R(i, t) &= P_i\{L > t\} \\ &= \sum_{j \in E} \int_{[0, t]} \tilde{R}(i, j, ds) \bar{G}_j(t - s) e^{-\lambda_j(t - s)}. \end{aligned} \quad (53)$$

Exponential Model in a Markovian Environment

A computationally tractable model is obtained when the environmental process Y is a Markov process so that $\bar{G}_i(t) = e^{-\mu_i t}$ and $Q(i, j, t) = P(i, j)(1 - e^{-\mu_i t})$. In this case, by stopping the Markov process Y at the system lifetime L , we obtain another Markov process

$$Z_t = \begin{cases} Y_t & \text{if } t < L \\ \Delta & \text{if } t \geq L \end{cases} \quad (54)$$

with state space $E \cup \{\Delta\}$ where Δ is an absorbing state and its generator is

$$A(i, j) = \begin{cases} -(\mu_i + \lambda_i) & \text{if } j = i \\ \mu_i P(i, j) & \text{if } j \neq i \end{cases} \quad (55)$$

for $i, j \in E$. Moreover, $A(i, \Delta) = \lambda_i$ and $A(\Delta, j) = 0$ for all $i \in E$ and $j \in E \cup \{\Delta\}$. The solution of (53) can now be obtained explicitly by noting that

$$R(i, t) = P_i\{L > t\} = P_i\{Z_t \in E\} = \sum_{j \in E} e^{tA}(i, j), \quad (56)$$

where e^{tA} is the matrix exponential defined by (35). This follows by observing that the transition function of a Markov process is given by the matrix exponential of its generator. Çekyay and Özekici [26] provide theoretical derivations and numerical illustrations on the reliability, mean time to failure, and availability of Markovian systems discussed in this section.

STOCHASTIC MIXED-INTEGER PROGRAMMING ALGORITHMS: BEYOND BENDERS' DECOMPOSITION

SUVRAJEET SEN

ISE Department, Ohio
State University,
Columbus, Ohio

INTRODUCTION

As discussed elsewhere in this volume, stochastic programming models provide an entrée into decision-making problems in which data uncertainty is best viewed through the lens of random variables or stochastic processes. There are numerous applications in which the need to address strategic issues in decision making leads to stochastic mixed-integer programming (SMIP) models. The breadth of examples considered in the literature include applications in inventory management [1], manufacturing capacity planning [2], process engineering [3], production scheduling [4,5], server location [6], supply chain planning [7], vehicle routing [8], and many more. These models arise in situations where the “lumpy” nature of decisions are coupled with forecast uncertainty. Failure to accommodate uncertainty can lead to plans that are “brittle,” in the sense that minor excursions from the norm may bring such systems to a grinding halt. Unfortunately, the study of SMIP problems is relatively recent, and many open issues remain. It is our hope that this article will kindle an interest in SMIP, and give readers the starting point to explore new properties and algorithms in this area.

While deterministic mixed-integer linear programming (MILP) methodology has made significant strides in the past several decades (see other articles in this volume), it is worth mentioning that these methods are often

inadequate for the direct solution of SMIP problems due to the explosion in the size of the deterministic equivalent MILP. The key to solving SMIP problems is the development of new decomposition algorithms for specially structured MILP problems. In this article, we will cover SMIP algorithms that may be looked upon as being in the same genre as Benders’ decomposition [9]. However, the reader will soon recognize that the mathematical and computational differences are significant.

SMIP problems involve models in which decisions and observations form an interleaving sequence, with decisions in earlier stages affecting future choices. As one might expect, the key to designing effective algorithms for solving such problems lies in the ability to assess the consequences of early decisions on future costs, and in this sense, value function approximations are important. Hence these models and algorithms share some affinity with dynamic programming [10].

Problem Setting and Classification

In this article, we will restrict ourselves to two-stage models, leaving the multistage SMIPs to more extensive surveys [11,12]. Moreover, to keep our focus on issues arising from integer restrictions, we will discuss the most common SMIP model, which uses “Expectation” minimization as a criterion. We do note, however, that the ability to include inequality constraints within an optimization model allows one to model more general risk measures without significant changes to the underlying structure of the problem.

To state the problem of interest, let $\tilde{\omega}$ denote a random variable defined on a probability space $(\Omega, \mathcal{A}, \mathcal{P})$ and X denote a constraint set specified by linear equations and inequalities. We use $\mathbf{X}$ to denote either the set of binary vectors $\mathcal{B}$, or integer vectors $\mathcal{Z}$ or even mixed-integer vectors $\mathcal{M} = \{x | x \geq 0, x_j \text{ integer}, j \in J_1\}$, where J_1 is a given index set consisting of some or all of the first-stage

variables $x \in \mathbb{R}^{n_1}$. Then the two-stage SMIP model may be stated as given in Equations (1–2c).

$$\text{Min}_{x \in X \cap \mathbf{X}} c^\top x + E[h(x, \tilde{\omega})], \quad (1)$$

where

$$h(x, \omega) = \text{Min } g(\omega)^\top y \quad (2a)$$

$$W(\omega)y \geq r(\omega) - T(\omega)x \quad (2b)$$

$$y \geq 0, y_j \text{ integer}, j \in J_2, \quad (2c)$$

where J_2 is an index set that may include some or all the variables listed in $y \in \mathbb{R}^{n_2}$. Given x , the above notation implies that the random variable $\tilde{\omega}$ induces another random variable $h(x, \tilde{\omega})$ whose outcomes are denoted by $h(x, \omega)$. Throughout this article, we will assume that all realizations $W(\omega)$ are rational matrices of size $m_2 \times n_2$. Whenever J_2 is nonempty, and $|J_2| \neq n_2$, Equation (2) is said to provide a model with mixed-integer recourse. We will also assume that the random variables have finite support, so that the expectation in Equation (1) reduces to a summation. Although Equation (2) is stated as though the random variable influences all data, most applications lead to models that lead to only some data uncertainty, which in turn leads to certain specialized models.

The degree of difficulty associated with SMIP varies significantly with the nature (binary or integer) of the “lumpy” decisions, as well as, the stages in which they arise. Accordingly, we begin by classifying SMIP problems according to the kinds of decisions that appear in different stages of the problem. Let

$B \equiv \{\text{The set of stages in which the model has Binary decisions}\},$

$C \equiv \{\text{The set of stages in which the model has Continuous decisions}\},$

$D \equiv \{\text{The set of stages in which the model has Discrete decisions}\}.$

For stochastic linear programs (SLPs), the sets B and D are empty, whereas, SMIP problems are devoted to instances in which these sets are nonempty.

The first observation regarding SMIP models relates to instances that satisfy $B = D = \{1\}$. Such instances can be solved by using the original version of Benders' decomposition. However, for instances in which $2 \in B \cup D$, Benders' decomposition in its original form is no longer applicable, and such SMIP instances require the use of more recently developed mathematical and computational machinery. In the interest of space, we will restrict our attention to algorithms that are applicable to two-stage SMIP problems for which $B = \{1, 2\}$, $C = \{2\}$, and either $D = \emptyset$ or $D = \{2\}$. While the case of $B = D = \{1\}$, and $C = \{1, 2\}$ is adequately covered through standard Benders' decomposition, we mention Norkin *et al.* [13], which discusses an approach in which the second-stage value functions are approximated using sampling methods within a branch-and-bound (B&B) search. This approach is particularly relevant for instances that require the second stage value function to be approximated by sampling [14,15].

MATHEMATICAL PROPERTIES AND COMPUTATIONAL COMPLEXITY

Because the value function of integer programming problems are notorious for their lack of convexity, and even the lack of continuity, it is interesting to identify circumstances under which one may obtain continuity of the expected recourse function. Schultz has shown that the expected recourse function satisfies the following [16].

Proposition 1. *Assume that Equation (2) has randomness only in $r(\tilde{\omega})$, and let the probability space of this random variable, denoted $(\Omega, \mathcal{A}, \mathcal{P})$, be such that $\mathcal{P}$ is absolutely continuous with respect to the Lebesgue measure in $\mathbb{R}^{m_2}$. Moreover, suppose that the following hold.*

- (a) *(Dual Feasibility). There exists $\theta \geq 0$ such that $W^\top \theta \leq g$.*
- (b) *(Complete Recourse). For any choice of $r(\omega)$, the MILP feasible set is nonempty.*
- (c) *(Finite Expectation). $E[\|r(\tilde{\omega})\|] < \infty$.*

Then, the expected recourse function is continuous.

It so happens that the requirement of absolute continuity (with respect to the Lebesgue measure in $\Re^{m_2}$) is rather restrictive from the point of view of practical optimization models. In order to appreciate this, observe that many practical LP/IP models have constraints that are entirely deterministic; for example, flow conservation/balance constraints often have no randomness in them. Formulations of this type (where some constraints are completely deterministic) fail to satisfy the requirement that the measure $\mathcal{P}$ is absolutely continuous with respect to the Lebesgue measure in $\Re^{m_2}$.

Intuitively, one recognizes that SMIP problems are at least as hard as MILP problems because any instance of the latter can be reduced to an SMIP. Formal analysis of the complexity of both stochastic linear as well as stochastic combinatorial optimization problems (i.e., $B = \{2\}$) rely on reduction of graph reliability problems to stochastic programming [17]. The reduction used in Dyer and Stougie [17] allows one to conclude that these optimization problems are $\#P$ -hard, where the class $\#P$ denotes counting problems for which membership to a set of items to be counted can be decided in polynomial time. Indeed, Dyer and Stougie [17] actually shows that the evaluation of the expected recourse function is itself NP-hard for a given first-stage vector x . Nevertheless, for certain special structures (assuming certain similarities between the first- and second-stage variables and objective functions) fully polynomial time approximations can be obtained for two-stage stochastic linear programming problems [18]. These ideas have also been applied to SMIP by using rounding to get integer solutions. However, it is an open question whether such methods can be extended to standard applications of SMIP where the stages ordinarily represent different aspects of strategic (e.g., location) planning and tactical (e.g., assignment) responses.

A GENRE OF SMIP ALGORITHMS

One of the more important requirements for stochastic programming algorithms is their ability to accommodate a large number of scenarios so that realistic applications can be addressed. For SLP, this observation has led to novel decomposition algorithms, some of which are deterministic procedures [19], while some others are stochastic [14,20]. On the basis of current evidence for SMIP problems, it appears that decomposition approaches look most promising [21,22].

A Unifying Framework for SMIP Benders' Decomposition

We begin by reiterating that our focus will be on cases for which $2 \in B \cup D$, so that the standard version of Benders' decomposition is not applicable because the expected recourse function (MILP value function) is nonconvex. Nevertheless, a conceptual extension of Benders' decomposition [23] has been designed for SMIP. While this scheme does not lead to a practical algorithm, it helps to highlight some of the challenges raised by these problems.

In order to maintain simplicity in this presentation, we assume that the second-stage problem satisfies the complete recourse property. Assuming that the random variable modeling uncertainty is discrete, with finite support ($\Omega = \{\omega^1, \dots, \omega^N\}$), a two-stage SMIP may be stated as

$$\text{Min } c^\top x + \sum_{\omega \in \Omega} p(\omega) g(\omega)^\top y(\omega) \quad (3a)$$

$$\text{s.t. } Ax \geq b \quad (3b)$$

$$T(\omega)x + Wy(\omega) \geq r(\omega), \forall \omega \in \Omega \quad (3c)$$

$$(x, \{y(\omega)\}_{\omega \in \Omega}) \geq 0, x_j \text{ integer}, j \in J_1, \\ \text{and } y_j(\omega) \text{ integer}, \forall j \in J_2. \quad (3d)$$

Despite the fact that there are several assumptions underlying Equation (3), it is somewhat general from the IP point of view since both the first- and second-stage variables allow general mixed-integer problems.

Suppose now that we wish to apply a resource directive decomposition method (i.e.,

Benders' decomposition). At iteration k of such a method, we solve one second-stage subproblem for each outcome ω , and assuming that there is an appropriate solution method for the second stage, we can obtain a nondecreasing price function $h_k^\omega(\cdot)$ for each outcome $\omega \in \Omega$ [24]. Consequently, we obtain a "cut" of the form

$$\eta \geq \bar{h}_k(x) := \sum_{\omega \in \Omega} p(\omega) h_k^\omega(r(\omega) - T(\omega)x). \quad (4)$$

Hence, as iterations proceed, one obtains a sequence of relaxed master programs of the following form.

$$\text{Min } c^\top x + \eta \quad (5a)$$

$$\text{s.t. } Ax \geq b \quad (5b)$$

$$\eta \geq \bar{h}_t(x), \quad t = 1, \dots, k \quad (5c)$$

$$x \geq 0, x_j \text{ integer}, j \in J_1. \quad (5d)$$

As with Benders' (or L-shaped) decomposition, each iteration augments the first-stage approximation with one additional collection of price functions as shown in Equation (5c). The rest of the procedure also mimics Benders' decomposition in that the sequence of objective values of Equation (5) generate an increasing sequence of lower bounds, whereas, the subproblems at each iteration provide values used to compute an upper bound. The method stops when the upper and lower bounds are sufficiently close. Provided that the second-stage problems are solved using B&B, it is not difficult to show that the method must terminate in finitely many steps. Of course, finiteness also presumes that Equation (5) can be solved in finite time.

Unfortunately, there are several algorithmic and computational questions that this conceptual method leaves unanswered. From an algorithmic point of view, there is no recommendation regarding the choice of price functions, and from a computational point of view, it is not clear that such a master program, which is nonconvex, can be solved to global optimality in reasonable time. Yet, the general structure of the scheme is appealing because it generalizes traditional

Benders' decomposition. The remaining algorithms presented in this article will differ from the one above in the manner in which Equation (4) is approximated, thus simplifying the solution of Equation (5).

SMIP Benders' Decomposition with Combinatorial Approximations

Unlike the price functions used in the previous section, Laporte and Louveaux [25] devised a method that uses combinatorial approximations. The algorithmic setting within which the inequalities of Laporte and Louveaux [25] are used follows the basic outline of Benders' decomposition. That is, at each iteration k , we solve one master program, and as many subproblems as there are outcomes of the random variable.

For this section, we allow $B = \{1, 2\}$, $C = \{2\}$, and $D = \{2\}$ in Equations (1) and (2). The approximation presented here can be applied to a wide class of expected recourse functions, so long as the first-stage decisions are binary, and we have a known lower bound on the expected recourse function. Interestingly, despite the nonconvexity of value functions of second-stage problems, the valid inequality provided by Laporte and Louveaux [25] is affine.

At iteration k , let the first-stage decision x^k be given, and let

$$I_k = \{i | x_i^k = 1\}, \quad Z_k = \{1, \dots, n_1\} - I_k.$$

Next define the affine function

$$\delta_k(x) = |I_k| - \left[\sum_{i \in I_k} x_i - \sum_{i \in Z_k} x_i \right]. \quad (6)$$

It is easily seen that when $x = x^k$ (assumed binary), $\delta_k(x) = 0$; whereas, for all other binary vectors $x \neq x^k$, at least one of the components must switch "states." Hence, for $x \neq x^k$, we have

$$\left[\sum_{i \in I_k} x_i - \sum_{i \in Z_k} x_i \right] \leq |I_k| - 1, \text{ i.e., } \delta_k(x) \geq 1. \quad (7a)$$

Next suppose that a lower bound on the expected recourse function, denoted $\bar{L}$, is

available. Let $\bar{h}_k$ denote the value of the expected recourse function for a given x^k . If $\bar{h}_k = \infty$ (i.e., the second-stage is infeasible), then Equation (7a) can be used to delete x^k . On the other hand, if $\bar{h}_k$ is finite, then the following inequality is valid:

$$\eta \geq \bar{h}_k(x) := \bar{h}_k - \delta_k(x)[\bar{h}_k - \bar{L}]. \quad (7b)$$

Here the term *valid* implies that the inequality does not delete any point of the epigraph of the expected recourse function. This is the “optimality” cut of Laporte and Louveaux [25], and is used in place of Equation (4). Finally, we should mention that such cuts can be strengthened using any special structure that can be exploited [22].

SMIP Benders' Decomposition with Disjunctive Programming: Set Convexification

This algorithm combines disjunctive programming ideas within the framework of Benders' decomposition, and is therefore referred to as *disjunctive decomposition*. In the previous two algorithms, each iteration requires the solution of multiple NP-hard subproblems (one for each scenario). The algorithm described in this section requires the solution of several LP subproblems, and as a result, one has greater control on the amount of computational effort in any given iteration [26]. This algorithm imposes the following structure on Equations (1) and (2): a fixed recourse matrix (W), $B = \{1, 2\}$, $C = \{2\}$, $D = \{2\}$. The methodology here is one of sequential convexification of the mixed-integer recourse problem. Such an approach (sequential convexification) provides stronger relaxations in later iterations, thus easing the computational burden. Note that cuts for this class of methods can also be derived using the RLT framework [27].

We start this development with the assumption that by using appropriately penalized continuous variables, the subproblem remains feasible for any restriction of the integer variables $y_j, j \in J_2$. Let x^k be given, and suppose that matrices $W_k, T_k(\omega)$, and $r_k(\omega)$ are given. Initially (i.e., $k = 1$) these matrices are simply $W, T(\omega)$, and $r(\omega)$, and recall that in our notation, we include

the constraints $-y_j \geq -1, j \in J_2$ explicitly in $Wy \geq r(\omega) - T(\omega)x$. (Similarly, the constraint $-x \geq -1$ is also included in the constraints $x \in X$.) During the course of solving the 0-1 MILP subproblem for outcome ω , suppose that we solve the following LP relaxation:

$$\text{Min } g^\top y \quad (8a)$$

$$\text{s.t. } W_k y \geq r_k(\omega) - T_k(\omega)x \quad (8b)$$

$$y \in \mathbb{R}_+^{n_2}. \quad (8c)$$

Whenever the solution to this problem is fractional, we will be able to derive a valid inequality that can be used in all subsequent iterations. Let $y^k(\omega)$ denote a solution to Equation (8), and let $j(k)$ denote an index $j \in J_2$ for which $y_j^k(\omega)$ is noninteger for one or more $\omega \in \Omega$. To eliminate this noninteger solution, a disjunction of the following form will be used:

$$\mathcal{S}_k(x^k, \omega) = \mathcal{S}_{0,j(k)}(x^k, \omega) \cup \mathcal{S}_{1,j(k)}(x^k, \omega),$$

where

$$\mathcal{S}_{0,j(k)}(x^k, \omega) = \{y \in \mathbb{R}_+^{n_2} \mid W_k y \geq r_k(\omega) - T_k(\omega)x^k, -y_{j(k)} \geq 0\}, \quad (9a)$$

$$\mathcal{S}_{1,j(k)}(x^k, \omega) = \{y \in \mathbb{R}_+^{n_2} \mid W_k y \geq r_k(\omega) - T_k(\omega)x^k, y_{j(k)} \geq 1\}. \quad (9b)$$

The index $j(k)$ is referred to as the *disjunction variable* for iteration k . This is precisely the disjunction used in lift-and-project cuts [28]. However for SMIP problems, the objective function used for cut generation will be different (see Remark 1).

Let $\lambda_{0,1}$ denote the vector of multipliers associated with the rows of W_k in Equation (9a), and $\lambda_{0,2}$ denote the scalar multiplier associated with the variable $y_{j(k)}$ in Equation (9a). Let $\lambda_{1,1}$ and $\lambda_{1,2}$ be similarly defined for Equation (9b). Then the theory of disjunctive programming implies that if $(\pi, \pi_0(x^k, \omega), \omega \in \Omega)$ satisfy Equation (10), then $\pi^\top y \geq \pi_0(x^k, \omega)$ is a valid inequality for $\mathcal{S}_k(x^k, \omega)$. To simplify the notation in Equation (10) we drop the dependence on x^k , and will reintroduce it

and recognize the dependence on x following Remark 1.

$$\pi_j \geq \lambda_{0,1}^\top W_{jk} - I_j^k \lambda_{0,2} \forall j, \quad (10a)$$

$$\pi_j \geq \lambda_{1,1}^\top W_{jk} + I_j^k \lambda_{1,2} \forall j, \quad (10b)$$

$$\begin{aligned} \pi_0(\omega) &\leq \lambda_{0,1}^\top (r_k(\omega) - T_k(\omega)x^k), \\ \forall \omega &\in \Omega, \end{aligned} \quad (10c)$$

$$\begin{aligned} \pi_0(\omega) &\leq \lambda_{1,1}^\top (r_k(\omega) - T_k(\omega)x^k) + \lambda_{1,2} \\ \forall \omega &\in \Omega, \end{aligned} \quad (10d)$$

$$\begin{aligned} -1 &\leq \pi_j \leq 1, \forall j, -1 \leq \pi_0(\omega) \leq 1, \\ \forall \omega &\in \Omega, \end{aligned} \quad (10e)$$

$$\lambda_{0,1}, \lambda_{0,2}, \lambda_{1,1}, \lambda_{1,2} \geq 0, \quad (10f)$$

where

$$I_j^k = \begin{cases} 0, & \text{if } j \neq j(k) \\ 1, & \text{otherwise.} \end{cases}$$

Remark 1. Several objectives have been proposed in the disjunctive programming literature for choosing cut coefficients [29]. One possibility for SMIP problems is to maximize the expected value of the depth of cut: $E[\pi_0(\omega)] - E[y^k(\omega)]\pi$. We should note that the optimal objective value of the resulting LP can be zero, which implies that the inequality generated by the LP does not delete some of the fractional points $y^k(\omega)$, $\omega \in \Omega_k$. Here Ω_k denotes those $\omega \in \Omega$ for which $y^k(\omega)$ does not satisfy mixed-integer feasibility. So long as the cut deletes a fractional $y^k(\omega)$ for some ω , we may proceed with the algorithm. However, if we obtain an inequality such that $(\pi^k)^\top y^k(\omega) \geq \pi_0^k(\omega)$, for all $\omega \in \Omega_k$, then one such outcome should be removed from the expectation operation $E[y^k(\tilde{\omega})]$, and this vector should be replaced by a conditional expectation over the remaining vectors $y^k(\omega)$. Since the rest of the LP remains unaltered, the reoptimization should be carried out using a “warm start.” Other objective functions can also be used for the cut-generation process. For instance, we could maximize the function $\text{Min}_{\omega \in \Omega} \pi_0(\omega) - y^k(\omega)^\top \pi$.

For vectors $x \neq x^k$, the cut may need to be modified in order to maintain its validity. It can be shown that for any other x , one only

needs to modify the right-hand side scalar π_0 ; in other words, the vector π^k provides valid cut coefficients so long as the recourse matrix is fixed. This result is known as the *Common Cut Coefficients (C^3) Theorem* [26].

The LP used to obtain the common cut coefficients is known as the C^3 LP, and its solution $(\pi^k)^\top$ is appended to W_k in order to obtain W_{k+1} . In order to be able to use these coefficients in subsequent iterations, we will also calculate a new row to append to $T_k(\omega)$, and $r_k(\omega)$ respectively. These new rows will be obtained by solving some other LPs, which we will refer to as RHS-LPs. These calculations are summarized next.

Let $\lambda_{0,1}^k, \lambda_{0,2}^k, \lambda_{1,1}^k, \lambda_{1,2}^k \geq 0$ denote the values obtained from C^3 LP in iteration k . Since these multipliers are nonnegative, the C^3 Theorem [26] allows us to use these multipliers for any choice of (x, ω) . Hence by using these multipliers, the right-hand side function $\pi_0(x, \omega)$ can be written as

$$\begin{aligned} \pi_0(x, \omega) &= \text{Min}\{(\lambda_{0,1}^k)^\top r_k(\omega) \\ &\quad - (\lambda_{0,1}^k)^\top T_k(\omega)x, (\lambda_{1,1}^k)^\top r_k(\omega) \\ &\quad + \lambda_{1,2}^k - (\lambda_{1,1}^k)^\top T_k(\omega)x\}. \end{aligned}$$

For notational convenience, we put

$$\begin{aligned} \bar{v}_0(\omega) &= (\lambda_{0,1}^k)^\top r_k(\omega), \\ \bar{v}_1(\omega) &= (\lambda_{1,1}^k)^\top r_k(\omega) + \lambda_{1,2}^k, \end{aligned}$$

and

$$[\bar{\gamma}_\ell(\omega)]^\top = (\lambda_{\ell,1}^k)^\top T_k(\omega), \quad \ell \in \{0, 1\},$$

so that

$$\begin{aligned} \pi_0(x, \omega) &= \text{Min}\{\bar{v}_0(\omega) - [\bar{\gamma}_0(\omega)]^\top x, \bar{v}_1(\omega) \\ &\quad - [\bar{\gamma}_1(\omega)]^\top x\}. \end{aligned}$$

Being the minimum of two affine functions, the epigraph of $\pi_0(x, \omega)$ can be represented as the union of the two half-spaces. Hence the epigraph of $\pi_0(x, \omega)$, restricted to the set X will be denoted as $\Pi_X(\omega)$, and represented as

$$\Pi_X(\omega) = \cup_{\ell \in L} \mathcal{E}_\ell(\omega),$$

where $L = \{0, 1\}$ and

$$\mathcal{E}_\ell(\omega) = \{(\eta, x) \mid \eta \geq \bar{v}_\ell(\omega) - \bar{y}_\ell(\omega)^\top x, \\ x \in X\}.$$

Here $X = \{x \in \mathbb{R}^{n_1} \mid Ax \geq b, x \geq 0\}$, and we assume that the inequality $-x \geq -1$ is included in the constraints $Ax \geq b$. It follows that the closure of the convex hull of $\Pi_X(\omega)$ provides the appropriate convexification of $\pi_0(x, \omega)$. This process is carried out by solving a linear program patterned after a cut-generation LP of disjunctive programming [27]. However, to avoid confusion between cut generation and this particular scheme of convexification, we refer to the resulting LP as the RHS-LP. Unlike problem C^3 -LP however, this LP is solved for every outcome ω .

Given the limitations of this article, we refer the reader to Sen and Higle [26] for further details, including a specific formulation of RHS-LP, and a proof of finite convergence. However, it is important to emphasize one detail, which has a significant impact on algorithmic efficiency. The observation is that C^3 -LP is itself an SLP, and solving this problem using decomposition provides very encouraging computational results [21]. Some of these computational results will be summarized subsequently. The main iterative steps are summarized below. The stopping rule is the same as in standard Benders' decomposition.

Disjunctive Decomposition.

0. *Initialize.* Assume that x^1 is given, and $k \leftarrow 1$.
1. *Sequential Convexification in Stage 2.*
 - a. *(Solve the LP relaxation for all ω).* Given x^k , solve the LP relaxation of each subproblem, $\omega \in \Omega$.
 - b. *(Solve C^3 -LP).* Use Equation (10) to generate a cut [26]. Append the solution $(\pi^k)^\top$ to the matrix W_k to obtain W_{k+1} .
 - c. *(Solve RHS-LP).* Solve one RHS-LP per $\omega \in \Omega$, and derive $r_{k+1}(\omega)$, $T_{k+1}(\omega)$.
 - d. *(Solve a cut-enhanced LP relaxation for all ω).* Using $x = x^k$, and the

updated matrices $W_{k+1}, r_{k+1}(\omega)$, $T_{k+1}(\omega)$, solve an LP relaxation for each $\omega \in \Omega$.

2. *Derive a Benders' Cut for Stage 1.* Using the dual variables obtained from the solution of the LP relaxations in step 1(d), derive a Benders' cut (also L-shaped cut [30]) of the form $\eta \geq \bar{h}_k(x) := \alpha + \beta^\top x$. This affine function replaces the nonconvex function 4, and is appended to the master program whose objective function retains piecewise linearity and convexity of standard Benders' decomposition.
3. *Solve the Master Program.* Obtain x^{k+1} by solving the Benders' master program; $k \leftarrow k + 1$ and repeat from 1.

SMIP Benders' Decomposition with Disjunctive Programming: Value Function Convexification

This method allows disjunctive decomposition to be used with a branch-and-cut framework, and is abbreviated as D^2 -BAC [31]. While the subtitle above emphasizes value function convexification, we look upon this as an added feature which will complement set convexification due to D^2 . The D^2 -BAC method is designed to be applicable for instances in which $B = \{1, 2\}$, $C = \{2\}$, and $D = \{2\}$. Because D^2 -BAC uses a B&B search in the second stage, it allows an "approximate solve" of the second-stage problem by truncating the number of nodes explored in the B&B search tree. Moreover, note that a B&B search tree that is obtained for one scenario (ω) can be used to approximate the second-stage MILP associated with another scenario. Let $Q(\omega)$ denote the set of nodes of the B&B tree that have been explored for the subproblem associated with scenario ω . For any node $q \in Q(\omega)$, let $z_{q\ell}(\omega)$ and $z_{qu}(\omega)$ denote vectors whose elements are used to define lower and upper bounds, respectively, on the second-stage (integer) variables. In some cases, an element of z_{qu} may be $+\infty$, and in this case, the associated constraint may be ignored, implying that the associated dual multiplier is fixed at 0.

In any event, suppose that for a given $x \in X$, we wish to construct a lower bounding

approximation of the value function of the second-stage problem. The LP relaxation for node q may be written as

$$\begin{aligned} h_q^\omega(x) &= \text{Min } g^\top y \\ Wy &\geq r(\omega) - T(\omega)x \\ y &\geq z_{q\ell}(\omega), \quad -y \geq -z_{qu}(\omega). \end{aligned} \quad (11)$$

The LP in Equation (11) can be used to derive a lower bounding function for node q , that is, we obtain an inequality of the form

$$h_q^\omega(x) \geq \alpha_q(\omega) + \beta_q(\omega)^\top x.$$

Let $\mathcal{E}_q(\omega)$ denote the epigraph of the above affine approximation. Since the optimal value of the second-stage problem for a particular outcome (ω) is at least as large as the minimal lower bound, we obtain a lower bound on the subproblem value function for an outcome ω by defining a function

$$h^\omega(x) := \text{Min}_{q \in Q(\omega)} \alpha_q(\omega) + \beta_q(\omega)^\top x. \quad (12)$$

Since Equation (12) is a nonconvex function, using it directly in stage one would still result in a Benders' master program that is nonconvex. Nevertheless we can convexify Equation (12), thus leading to a more convenient master program. We, therefore, use disjunctive programming to derive a facet of the set

$$\mathcal{E}(\omega) := \cup_{q \in Q(\omega)} \text{clconv } \mathcal{E}_q(\omega).$$

For each $\omega \in \Omega$, a facet of $\text{clconv } \mathcal{E}(\omega)$ provides an affine lower bounding approximation of Equation (12). Taking expectations then yields an affine approximation, which replaces Equation (4), and once again, the objective function of Equation (5) remains piecewise linear and convex.

Convergence properties of the above process are discussed in Sen and Sherali [31] and computational results appear in Yuan and Sen [21]. Table 1 summarizes computational results that have appeared in the latter paper. These problem instances are stochastic server location problems (SSLPs) in which servers have to be located to meet demands, which may or may not be realized

Table 1. Comparative Computational Results [21]

SSLP	CPU (s)		
	D^2	D^2 -BAC	D^2 -BAC+SLP
5_25_50	1.64	0.70	0.36
5_25_100	2.15	1.73	0.89
5_50_100	7.10	3.70	1.56
5_50_500	34.50	23.05	12.36
5_50_1000	140.47	64.17	22.77
5_50_2000	603.37	274.40	42.74
10_50_50	295.95	373.98	262.13
10_50_100	396.76	452.31	486.99
10_50_500	1902.2	2772.22	1313.38
10_50_1000	5410.1	5677.80	2139.47
10_50_2000	9055.29	>10,800	3916.47
15_45_5	110.34	232.30	211.79
15_45_10	1494.89	222.41	153.41
15_45_15	7210.63	1988.26	803.56

in the future [6]. If demand is realized, then servers have to be allocated in such a way that capacity restrictions are satisfied and certain operating rules (e.g., servers can be only a specified distance from demand) must be satisfied, while meeting as much demand as possible. As shown in Ntamo and Sen [32] SSLP problems are essentially unsolvable without decomposition. (Here *unsolvable* refers to the inability to obtain an optimal solution within 10,000 s of computing on a Sun Fire 400 workstation.) However, Table 1 demonstrated that these are being solved to optimality using various versions of disjunctive decomposition (D^2). The earliest version, referred to as D^2 in Table 1, uses only set convexification, whereas the D^2 -BAC algorithm uses both value function and set convexification. The first two columns represent ideas that were implemented in Ntamo and Sen [32], and the column labeled D^2 -BAC+SLP refers to the implementation that uses a specialized SLP decomposition [21] to solve the cut formation LP (C^3 -LP). The improvements reported in Yuan and Sen [21] are clearly remarkable, considering that most of these instances are unsolvable using state-of-the-art deterministic MILP solvers [32].

The instances in Table 1 were first reported in Ntamo and Sen [6], and subsequently used as a test-bed for evaluating advances for this genre of decomposition algorithms. To appreciate the significance of some of the instances, we note that if one were to use a deterministic equivalent formulation of SSLP_10_50_2000, then the resulting problem would have at least 1 million binary variables ($10 \times 50 \times 2000$). In the decomposition framework, however, the number of first-stage variables is 10 and the number of second-stage variables is 500 (per scenario). Because of decomposition, the 2000 subproblems are solved independently, and as a result we are able to solve the high-dimensional deterministic equivalent by solving a collection of lower-dimensional problems. This is why decomposition is a winning strategy.

FURTHER CONNECTIONS WITH THE LITERATURE AND CONCLUSIONS

We have restricted this article to methods that can be viewed as the next generation of Benders' decomposition algorithms. While most of the methods presented in this article require the first-stage decisions to be binary, Sherali and Zhu [33] propose a search algorithm, which accommodates continuous variables in the first stage. The case of random recourse matrices has also been addressed in Ntamo [34].

In order to give the reader a brief picture of the SMIP landscape surrounding the class models stated in Equation (1)–(2) we mention the simple and/or complete recourse models studied in Klein Haneveld and van der Vlerk [35] and van der Vlerk [36]. Methods for this class fully exploit the structure of these problems by establishing connections with continuous recourse models. At the other end of the SMIP spectrum, we mention the pure SMIP models that have been studied using global optimization [37,38]. Finally, another important version of two-stage SMIP problems is the case of infinitely many scenarios (i.e., continuous random variables) [15]. This approach is based on an extension of stochastic decomposition [14], which

was originally designed for two-stage SLP problems.

The literature also makes several recommendations for multistage SMIPs as well [1,5,39]. This class of problems arises in several engineering applications in which system requirements evolve over time, and capacity/schedules must be adjusted to respond in an optimal way. The method discussed in Caroe and Schultz [5] was motivated by one such application in electricity operations scheduling. Despite the availability of basic methodology for multistage SMIP problems, there is clearly a paucity of computational work with these problems. It is likely that the basic multistage algorithms proposed in Lulli and Sen [1], Caroe and Schultz [5], and Alonso-Ayuso *et al.* [39] will need further enhancements using valid inequalities, such as those suggested in Guan *et al.* [40].

SMIP problems represent the next frontier of optimization research. Indeed, this area represents the union of applications that are addressed by SLP, and MILP, and the resulting impact cannot be overstated. It is just as clear that the computational challenges that need to be overcome are also significant. At this point in its development, theoretical as well as computational results look promising. As computational power grows over the next few decades, and further algorithmic advances are realized, we expect to see further successes and applications of SMIP models.

Acknowledgments

This research was supported, in part, by Air Force Office of Scientific Research (AFOSR) Grant FA9550-08-1-0154, and NSF grant CMMI - 0900070. This paper was started as part of a tutorial series given to Ph.D. students in the state of Ohio, under the banner "OR-Ohio." It was completed due to the patience and perseverance of Cole Smith and Shabbir Ahmed. Thanks are also due to the referees for their careful reading of the paper.

STOCHASTIC MODELING AND OPTIMIZATION IN BASEBALL

BRAD NULL
AOL Research, Santa
Barbara, California

Baseball players and teams have many opportunities to use operations research to maximize their chances of winning games and pennants. For example, a pitcher must determine what pitch to throw, whether to pitchout, or whether to intentionally walk the hitter. A batter must decide whether to swing, bunt, or hit and run. Fielders must determine where to position themselves, for example, whether or not to “play in” to attempt to prevent a runner on third base from scoring, and runners must know whether to steal, run on contact, or take the extra base on a hit. Beyond this, the manager has to pick a lineup, place them in a batting order, decide when and whom to substitute, and set a pitching rotation, while the general manager must decide who to draft, who to trade, who to release, who to pursue in free agency and arbitration, and how much money to offer them. Even higher up, decisions must be made about when to hire and fire the manager or general manager and whom to replace them with, how to set payroll and ticket prices, and other more general business decisions.

Optimized solutions to these problems can have a significant impact on the bottom line. For example, researchers have estimated that optimal pitch selection could be worth as many as 2 additional wins a year [1], optimal batting order selection as much as 3 additional wins [2], and optimal closer usage up to 4.5 wins [3]! The value of a single win for a Major League team has been estimated to be between \$750,000 and \$4.5 million [4]. Thus, it is no surprise that these teams have begun to take notice of these problems and look for better solutions [5].

This article reviews operations research techniques that can be and are used to address these problems, focusing on those geared toward improving a team's chances of winning games and championships. We organize these problems into three groups:

1. *On-Field Decisions*: determining what a batter, pitcher, runner, or fielder will do at any point in the game.
2. *Player Usage Decisions*: determining which players to use at which points in the game.
3. *Personnel Decisions*: determining who should be on the team.

In addressing these problems, this article assumes a basic understanding of the game of baseball. For a general reference about the game, please see one of the many fine reference books in this area, such as Ref. 6, or just head to the local ballpark. (Note: the focus of this article is not intended to diminish the importance of several other important avenues of baseball research relating to such topics as scheduling, draft management, and stadium and operations planning and management; see Refs 7 and 8 for an introduction to some of these areas.)

ON-FIELD DECISION MAKING

By on-field decision, we are referring to a decision made by (or at least executed by) a player or players on the field. In this section, we review approaches used to address the various on-field decisions faced by pitchers, batters, fielders, and runners. Given the large number of such decisions, and the significant overlap in techniques used to address them, this section is organized according to analytical methods as opposed to particular decision problems. (While sample applications are discussed herein, references abound with more focused discussion of modeling related to the particular decision problems faced by

pitchers [1,9–11], batters [12–14], fielders [9,15], and baserunners [9,16].)

There are two key requirements to adequately model such on-field decisions (as there are with any decision analysis problem). These are as follows:

1. A reliable assessment of the probability of any outcome given any decision.
2. An understanding of the value of each possible outcome. These values can be in terms of the change in win probability of the action, the change in expected runs scored due to the action, or some other metric.

Given these two sets of information, determination of the optimal strategy is straightforward. As a simple example, consider a batter deciding whether or not to sacrifice bunt with a runner on first base and no outs in the bottom of the ninth inning. Assume that if the batter bunts he is always successful, resulting in the runner being advanced to second and the batter being thrown out. In this case, the batter's team will win 80% of the time. If the batter does not bunt, he gets a hit 30% of the time, resulting in the runner advancing to second base and the batter going to first base with no outs, which would result in the batter's team winning the game 90% of the time. Otherwise, the batter gets out and the runner remains at first base, in which case the batter's team wins 75% of the time. Thus, in the first case, the batter's team wins 80% of the time, and in the latter it wins 79.5% ($0.30 \times 0.90 + 0.70 \times 0.75$) of the time, so it would be slightly preferable for the batter to bunt. Of course, this is a simplified example, and there are significantly more play result possibilities and several ways of assessing these probabilities and values. In the remainder of this section, we focus on the various stochastic modeling techniques of use in assessing these quantities, as well as how to optimize decisions given these values.

Assessing Play Result Probabilities

We separate the primary methods of assessing play result probabilities into three categories according to their specificity: (i) average case probabilities, (ii) player-based probabilities, and (iii) probabilities assessed for specific plays. The main difference among the three lies in whether or not the abilities of the specific players involved are accounted for in the estimates. Average case methods do not account for specific player abilities; player-based methods generally account for either the batter or pitcher, and play-based methods account for both.

Average Case. Average case evaluation is the simplest approach to estimating play result probabilities. The basic approach aggregates historical data from a large set of games or plate appearances (associated with a large set of players) in which a particular action was taken—counting the historical frequency of the different possible results over these plate appearances. For example, to estimate the transition probabilities of “swinging away” in each of the 24 possible base out states in an inning (3 possible out states—0, 1, or 2, multiplied by eight possible combinations of runners on base— $2 \times 2 \times 2$), we might look at the total number of times a batter attempted to get a hit in each state over the course of a season, and the number of times each possible successor state was visited immediately afterward. This sort of analysis can also be used with respect to other actions. For example, in analyzing the sacrifice bunt, Tango *et al.*, look at all bunt attempts between 2000 and 2004, segmenting them in various ways, for example looking at bunt attempts by nonpitchers before the seventh inning with a runner on first base and no outs, to estimate the general probabilities of various results given such a strategy [9].

Player-Level Estimates. While average case analysis can be useful when pursuing general insight into decisions, the actual abilities of specific players vary wildly across numerous dimensions, and it is generally insightful to account for this when assessing optimal strategies for specific teams. While the most

obvious and direct method to estimate these probabilities would simply be to use a player's historical statistics to estimate his personal probabilities, this approach suffers from two common problems. First, there is often insufficient data to generate a reliable estimate. For example, most players attempt to bunt no more than a handful of times in a season, providing too little data with which to form any sort of estimate of ability. In addition, player performance generally suffers from the well-documented regression to the mean effect, meaning that players who have historically performed much better than the average player will not tend to maintain this high level of performance in the future (although they do frequently perform somewhat better than average), while players who perform worse than average will tend to improve somewhat in the future (if given the chance). For more on this phenomenon and its origins, see Ref. 17.

Precisely because of these sorts of issues, much energy has been devoted to developing models and projections of player ability and performance (see Ref. 18 for a comparison of the performance of a representative sample of them), many of which are quite complicated and estimate not just a player's underlying ability at a specific point in time but also factors that might affect a player's performance over time such as age, stadium, and year-to-year variance in performance.

Of particular interest for our applications are Bayesian approaches, which generate a prior distribution of player ability for specific populations of Major League players, meaning that any randomly selected player in this population could be viewed as having been drawn from this underlying ability prior distribution. Given this prior, adding evidence about a player (historical data) allows us to update the distribution and derive a posterior distribution for that specific player. These models have several attractive properties. First, they provide a framework for attempting to separate the inherent randomness in performance from the underlying ability; that is, account for the aforementioned regression to the mean effect. They

also make it very easy to deal with new players by simply assigning them the population prior distribution, and are often particularly easy to update as new information is gathered (particularly those based on Beta distributions such as in Refs 19 and 20, which are conjugate to multinomial data). In addition, they can be used to estimate abilities and likely results on a granular level (i.e., with respect to any specific possible outcome such as a strikeout or a home run) given any set of data. Most importantly though, such models have been shown to fit the data very well compared to other approaches, as well as possess excellent predictive power [20].

These sorts of models can also be applied to estimate baserunning and other abilities and can be modified to incorporate other environmental effects. Of course, very sparse data (such as a few observations per player) may lead to little separation in the estimates of the abilities of different players, but this is better than the alternatives of either assigning the same estimate to all players or using very sparse data to generate a point estimate.

Play-Level Estimates. Even more specific than player-level models are models that estimate the probabilities of the various outcomes of a specific game situation incorporating the influences of both the batter and the pitcher. One early and elegant model to estimate the probability of a particular result given a specific batter and pitcher (and their associated likelihoods) is the log5 model of James [21]. The general form of this model is

$$p(y) = \frac{\frac{x_b x_p}{x_l}}{\frac{x_b x_p}{x_l} + \frac{(1-x_b)(1-x_p)}{1-x_l}},$$

where $p(y)$ represents the probability of a specific outcome (e.g., probability of getting a hit), x_b and x_p represent the batter's and pitcher's individual probabilities with respect to the result in question, and x_l represents the league average. One key benefit of this model is that no parameterization is required. Given an assessment of the ability of the batter and pitcher, we can

immediately produce an assessment of the expected performance when they face each other. Further, many researchers have also commented on the good fit of this model to actual data [22].

In these models, as well as average case and player-based models, it is often important to account for other situational factors, such as the impact of the particular stadium, home field advantage, and handedness effects. Some of these effects have been estimated in isolation via various methods such as regression-based approaches (see Ref. 23 and its references for a comparison of such efforts to estimate stadium effects). Regression-based or curve-fitting approaches can also be used to attempt to estimate the impact of several effects at once, as well as generate an alternative model to the log5 for estimating the probability of particular play outcomes under certain conditions. An implementation of such a linear model is in Ref. 14, including a cautionary note about when such modeling of particular effects may or may not be appropriate. Finally, an extension of the log5, referred to as the *odds ratio method* has also been proposed to incorporate additional factors as well [24].

Estimating Outcome Values

Given some estimate of the probability of any play outcome, the question remains as to what is the value of that outcome. As mentioned above, the general goal of on-field decisions is to maximize the probability of winning the game. Thus, we would ideally like to determine the value of any play outcome in terms of the resulting probability or probability added of winning the game, although at times it may be useful to also quantify the value in terms of expected runs generated or some other metric. We discuss these various approaches below.

Markov Chains and Win Probability. One valuable concept that has been employed extensively for this task (since at least Howard in 1960 [25]) is the use of Markov models. One typical implementation of such (for example, in Refs 10 and 26) defines the state of a game as a 7-tuple composed of the following pieces of information:

- Inning
- Half inning
- Outs
- Orientation of the runners on base
- Lineup spot of the next batter for the visiting team
- Lineup spot of the next batter for the home team
- Home team runs scored minus visiting team runs scored.

Capping the run differential at ± 10 runs, modeling any extra inning as the ninth (i.e., if the teams are tied at the end of the ninth inning, we assume the next inning is also the ninth—an equivalent representation), and assuming a fixed lineup, gives 734,832 possible states. Thus, such models are generally very tractable for typical Markov chain analysis.

Using one of the methods discussed in the previous section we can either directly calculate the transition probabilities for this chain (i.e., the probability of any successor state as defined by the above 7-tuple given the current state) or else assess the likelihood of more conventional play results (e.g., strikeout or home run). In the latter case, we would then need a mapping from event types to resulting states given the current state. Such a mapping can be generated using historical data as in Ref. 14, a simple heuristic as in Ref. 27, or via another method.

In such chains, there are a limited number of possible successor states for any given state. Also, the states can be ordered chronologically (except for the potentially recurring ninth inning). These facts make calculating values of interest (e.g., the probability of either team winning, the distribution of the final score, etc.) with respect to this Markov chain considerably easier, and faster (see Ref. 14 for a thorough discussion of these points). To calculate these values, we can begin with all states that represent the end of the game and assign each a one or zero according to whether or not a selected team would have won the game in that state. Then, move backward among the states chronologically, determining the value of each state by multiplying the probability of transitioning

to each possible successor state from that state by the previously determined value of said successor state. This is exactly the backwards induction technique of dynamic programming, and thus different alternatives throughout the game can also be easily incorporated within this approach to convert this decision analysis approach into a full-scale dynamic program. (See the section titled “Dynamic Programming” in this encyclopedia for more on this general subject.)

This methodology is applied in Refs 10 and 14 in conjunction with player- and play-based transition models respectively to formulate optimal policies with respect to intentional walks and bunts for each of the 700,000 + possible states for specific matchups and games. The results in Ref. 14 also showed that context matters; that is, the optimal policy (with respect to bunting) can vary wildly from game to game as can the value of such optimization. Solving the dynamic program over 100 games from the 2007 season with transition probabilities derived using a Bayesian model of player ability, the percentage of states in which bunting was optimal varied between 7 and 17%, depending upon the specific team and opponent. A modified version of this approach was also used in Ref. 9 to construct average case Win Expectancy tables, which were then used to develop rules of thumb for optimal strategies with respect to bunts, steals, and intentional walks, incorporating some key elements of the associated players’ abilities.

Until now, we have glossed over the relatively strong Markov assumption that this approach makes, which requires that the transition probabilities are known and fixed from the beginning of the game. However, if player abilities are unknown, as represented in the Bayesian models of ability discussed in the section titled “Player Level Estimates,” and/or changing, this assumption does not hold. The impact of the first of these issues (unknown ability) was tested in Ref. 14 on actual games by comparing results generated via the Markov chain approach with results generated via simulation on both player ability and play results. While this research did show pitfalls of using Markov-based analysis

to evaluate season level results (different game outcomes are not independent!), it concluded that there is no discernable difference in game level predictions for the two models beyond the expected simulation error. The latter issue (changing ability) is a thornier one, particularly with respect to changes correlated with in-game performance; i.e. momentum. Debates have raged for years about whether or not momentum even exists in sports at all, and thus we leave that issue to another forum [28].

Run Expectancy. By slightly altering the state space and the value function, the Markov model from the previous section can also be used to estimate the expected number of runs scored in the remainder of a game or inning given a current state and transition matrix (as in Ref. 9 or 29). Bellman hypothesized that maximizing run expectancy may be a good proxy for maximizing win probability early in the game [30], although results in Ref. 10 indicate that optimal decisions under the two criteria can vary considerably. Nonetheless, while the output of such a model should be used with care, this approach significantly reduces the complexity of both the analysis and the ultimate output. As a result, the approach is quite common. For example, Ref. 9 takes this approach to create more general rules of thumb than those mentioned in the previous section.

Alternate Metrics. Simplifying things even further, some researchers have chosen to bypass the Markov chain framework altogether and use other metrics to evaluate possible outcomes. For example, in Ref. 1, optimal pitch selection is evaluated using the newly popular OPS statistic (on-base percentage plus slugging percentage) as the metric of choice. As discussed therein, OPS has been shown to be highly correlated with run production, which in turn has been closely tied to win percentage (namely, via the oft used Pythagorean theorem of baseball [31,32]). Thus, the hope of such an approach is that selecting the alternative to maximize the expected OPS of a given at bat (or from the defense’s point of view to minimize expected

OPS) will in turn maximize the team's probability of winning the game. These sorts of approaches are especially useful for decisions that need to be made in many contexts and without much time to plan, like pitch selection and base running.

Game Theory

Thus far, we have focused exclusively on a single team's strategy within a game. However, every game has two teams with opposing objectives. Thus, there is a natural game theoretic component to any decision problem faced therein. In other words, any analysis of what one team might do must account for the actions the other team may or may not take. On one level, the impact of the opposing team is not terribly significant. Each team is still solving its own optimization problem and to do so needs only to assess the probability of different outcomes, which is based only on the likelihood that the opponent will take certain actions (not whether this behavior is optimal). This is a reasonable approach for a one-off decision. However, the sort of decision analysis discussed in this article generally only proves truly useful when applied to large numbers of games and situations. If such analysis led a team to radically alter its behavior, their opponents would likely respond by altering their behavior as well. For example, if a team determines that it is generally optimal for a specific player to steal when he is on first base, and the player implements this strategy by always stealing immediately, then soon that team's opponents will realize this and always pitchout on these occasions, increasing the probability that runner will be caught stealing and likely eliminating the advantage in this strategy. Thus, it is worthwhile to examine equilibrium strategy in baseball to better understand the optimal long term strategy with respect to situations like these. Owing primarily to data limitations, existing research in this area generally stops at examining whether players appear to be using optimal mixed strategies. Such work has examined such decisions as pitch selection [1,11] and bunting [9], frequently concluding that players do not seem to be mixing optimally.

Fortunately, many decisions in baseball are sequential, for example, first the pitcher decides whether or not to intentionally walk the batter, and then if the pitcher does not, the batter decides whether or not to bunt. These can be integrated directly into the dynamic programming framework outlined above and all optimal decisions can be solved for sequentially. Further, comparing the results of such optimizations to those derived from one sided optimization can illuminate the "path to equilibrium." For decisions that are truly simultaneous, such as in the steal/pitchout sub-game, equilibrium strategies can be solved for using standard techniques (see the section titled "Game Theory" for more on this topic), the respective optimal strategies, and more importantly the likelihoods of the different outcomes of the play, can then be modeled as a single decision point within a larger dynamic program modeling the entire game.

PLAYER USAGE DECISIONS

While on-field decisions account for a large proportion of the in-game decisions that must be made by baseball teams, we have intentionally avoided the discussion of one significant class of in-game decisions thus far, substitution. This is because this and other player usage decisions can be considerably more complex than the decisions we have dealt with to this point. Thus, it is often difficult to solve for optimal strategies for these decisions, requiring the search for approximately optimal strategies and use of heuristics. There are two key reasons for this additional complexity.

First, the objective often requires a wider scope; that is, we generally have to look beyond the current game to see the impact of these decisions. For example, choosing to use a player in a particular game can affect his availability (especially pitchers) in subsequent games. Also, the risk of fatigue and injury rise the more a player is used. Finally, given that we do not have perfect information about all players and their abilities, the more we use a player, the more information we gather on that player, the value of which

can be significant when deciding whether or not to use this player in future games.

Second, the model of a single game becomes necessarily more complex when we allow for substitution. Consider the Markov chain previously discussed with just over 700,000 states. If we allow for each team to use six relief pitchers and try to incorporate these possibilities into such a chain, the state space expands by a factor of 37,249 (see Ref. 14 for details on the calculations). Allowing for five possible pinch hitters multiplies the state space by a factor of 37,295,449! Given these issues, various approaches have been taken to limit the scope of these problems and derive insights. Below we highlight some recent results with respect to several player usage decisions including substitution, batting order selection, and setting of pitching rotations.

Substitution

The most straightforward way to analyze substitution alternatives is to implement the dynamic programming approach laid out in the section titled “Markov Chains and Win Probability” with respect to a pared down set of substitution possibilities. Hirotsu and Wright [26] took this approach, solving such a problem limited to three substitutes. Even with this limitation, their approach, implemented in 2003, took approximately 12h to solve one game! Despite the fact that processor speeds continue to improve, this highlights the importance of approximate techniques.

The authors in Refs 3 and 9 both took heuristic approaches utilizing the concept of leverage (defined as the ratio between how much a single run scored changes the probability of a team winning in the current situation vs how it would have changed their probability of winning at the beginning of the game). They used this concept to greatly reduce the complexity of the state space by defining every possible state by its leverage (and inning) and attempting to find an optimal benchmark strategy of the form that a particular type of substitute should be brought in if the current leverage is above a certain amount. For example, Woolner [3]

estimated that if a team were to bring its closer in any time, the leverage rises above 2.55 (with slightly different rules if it is the ninth inning or the closer is well rested); this would be worth an average of 1.6 wins per team over the course of a season.

Batting Order

Another important problem a manager faces daily is selecting a batting order. This problem has been studied in operations research circles since at least 1966 [12], and frequently with the incorporation of a Markov-chain-based analysis [29]. Again, the main problem with this approach is computational. There are $9!$ possible lineups (assuming the nine starters are preselected, otherwise there can be significantly more). Attempts to exhaustively search for the optimum among these many choices took 5.5 days for researchers in 1997 and 2h in 2003 [2]. While improvements in processor speed will continue to reduce this time, this is certainly another area where fast, nearly optimal heuristics could be of value. Two such approaches that have been taken recently include the application of decision rules [29] and classification of batters and logical class ordering [2]. The latter was shown to yield lineups with an expected run production within 0.1 runs of optimum on average, while running thousands of times faster than a program to solve for the optimal solution.

Other Usage Decisions

Other usage decisions a manager faces over the course of a season include actually picking which players to start in a game and setting a pitching rotation. One oft-debated question in this area concerns whether teams are benefited by the five man rotation that has become ubiquitous since the late 1980s versus the four man rotation common in the previous era. This decision differs from optimizing substitution or the batting order in that the issues here are not computational, but rather primarily a problem of estimating true fatigue effects. The difficulty of such estimation is highlighted by the fact that, in two recent analyses of the subject, Refs 9 and

33, one concluded that a five man rotation was optimal, the other recommended four!

All in all, while the work in this area to date has been informative, it is obvious that there is still much room for improved models and approaches to address these challenging problems. In particular, such approaches may benefit from more integration with Markov-chain- or simulation-based models of entire games (as much of the other research discussed herein has), perhaps applying approximate dynamic programming techniques (see the section titled Approximate Dynamic Programming in this encyclopedia for more on this topic) to address these much larger problems.

PERSONNEL DECISIONS

The final decisions we discuss are those involving the acquisition and dismissal of player personnel. How do teams decide who they want on their team and how much to pay them? Of course, the foremost consideration in determining whether or not to acquire a player is to estimate how well he will perform and the value of this performance. As mentioned in the section titled "Player-Level Estimates," much research has been devoted to creating systems to forecast player performance. Further, several metrics have been invented to value players (particularly in recent years), most of which value players in terms of expected runs created. See, for example, the Linear Weights methods detailed in Ref. 34. Given such values, follow-on analysis can use the commonly accepted convention that 10 runs is approximately worth 1 win to estimate the impact on wins and losses of given players. For example, this approach is taken in Ref. 4 to determine the value of Alex Rodriguez.

This value can be highly context specific. For instance, that same article calculated different values for different wins, determining that wins more likely to get a team into the playoffs are approximately six times more valuable than those with little effect on a team's pennant chances. Further, different players may be more valuable to certain teams due to other characteristics that cause

them to have a better "fit" with that team. For example, one classic hypothesis, discussed in Ref. 29, asserts that a team with a mix of players with a high propensity to reach base as well as players with a high propensity to hit home runs can generate more runs than a team with players of just one type or the other. Additionally, given that we may be more certain about the ability of certain players (i.e., those with a large amount of Major League experience), there may be a team-varying value of this certainty. For example, a high-variance player ("high upside") may be more valuable to team just on the outside of making the playoffs, while a dominant team may prefer the known quality ("proven veterans") even though they both have the same expected ability. Initial analysis to attempt to measure such effects [14] indicates that different players do have significantly different effects on different teams. In a small sample of experiments, this value for particular players ranged by up to 2 wins.

FRONTIERS

This article has highlighted just some of the operations research problems, methods, and results in baseball today. In the coming years, such models will certainly be expanded upon and potentially rewritten. Of particular interest in the near future will be models derived from new data that is providing much more granular information about the game, such as the precise location and movement of individual pitches [35], or the precise positioning and movement of the fielders on each play. Such data is opening up additional problems to quantitative analysis, such as player positioning and pitch selection, as well as new methods to address these problems. This, as well as the ongoing leveraging of more and more advanced operations research techniques, will continue to expand the horizons of our knowledge of optimal strategies in baseball.

STOCHASTIC NETWORK INTERDICTION

DAVID P. MORTON
Graduate Program in Operations
Research, The University of
Texas at Austin, Austin,
Texas

INTRODUCTION

A prototypical interdiction model involves two adversaries, a leader and a follower. In this article, we begin by illustrating ideas through a shortest-path network interdiction model, where the follower seeks a shortest path in a directed network. Before the follower does so, the leader can first lengthen (interdict) some of the arcs in the network, under limited resources, to maximize the length of the follower's shortest path. We begin with *deterministic* shortest-path interdiction before turning to the stochastic case. This serves to set ideas and notation in a simpler setting. More importantly, it allows us to distinguish formulation techniques and algorithmic tools that work well in both settings from those specific to the deterministic case. With the same motivation, we also consider deterministic and stochastic models for interdicting a maximum-reliability path.

We focus on the interdiction of shortest-path, and maximum-reliability-path, networks for concreteness, but these should be viewed as proxies for a more general model of operations. For example, instead of a shortest-path problem, the operations problem can involve critical infrastructure such as a municipal water system [1], a communications network [2], an electric power system [3,4], or a petroleum reserve [5]. Alternatively, the operations problem can involve transport of illicit nuclear material, or a weapon, across a transportation network [6,7] or can involve a rogue country's program to build a first nuclear weapon [8]. In the

former cases, "we" may be the follower, that is, we operate the infrastructure. And, in this setting, we seek to understand our system's vulnerability to attack by formulating an interdiction model so that we may thwart such an attack. Alternatively, we may seek to disrupt operation of an adversary's critical infrastructure, and so we may be the leader. Indeed, in the latter set of examples, we are the leader, seeking to interdict such an adversary.

Several fundamental ideas in optimization modeling and algorithms come to the fore in this article. Our core interdiction problem is naturally formulated as a nested "max-min" model with the outer decision variables being discrete and the inner minimization being a linear program. Such a model cannot be solved by standard optimization software. That said, fixing the variables of the outer maximization, and taking the dual of the inner linear program (LP) leads to a nonnested mixed-integer program (MIP), which can be solved by standard software. We find it appealing that duality plays such an integral role in simply formulating a tractable optimization model. We also describe an interdiction model where direct application of this idea fails to yield a linear MIP. Here, we instead achieve a linear MIP by using an exact-penalty reformulation of the inner LP. We develop special-purpose Benders' decomposition algorithms for the interdiction models we consider. The network nature of our problems leads to particularly transparent master programs, that is, models that can be written down immediately as being obviously correct formulations. This basic decomposition algorithm is enhanced by valid inequalities that use a simple logical construct, that is, the inequalities condition on whether the leader interdicts at least one arc on paths attractive to the follower.

The section titled "Deterministic Shortest-Path Network Interdiction" relies heavily on Israeli and Wood [9], and describes deterministic interdiction of a shortest path model in which the follower's source (s)

and terminus (t) are known to the leader. The section titled “Stochastic Shortest-Path Network Interdiction” generalizes this to the case where the follower’s s - t pair is known to the leader only through a probability distribution. The sections titled “Interdicting a Maximum-Reliability Path: Known s - t Pair” and “Interdicting a Maximum-Reliability Path: Stochastic s - t Pair” consider a variant in which the leader minimizes the follower’s maximum-reliability path, first with a certain s - t pair and then with a stochastic s - t pair. The former is shown to be captured by the model of the section titled “Deterministic Shortest-Path Network Interdiction,” but the latter requires another approach. The last section summarizes.

To avoid excessive problem development with diminishing returns on modeling and algorithmic insights, in this article, we restrict attention to four related interdiction problems on shortest-path and maximum-reliability networks. However, before proceeding, we point to work on interdiction of another classic network-flow problem, a maximum-flow network. Deterministic maximum-flow network interdiction is studied by Phillips [10] and Wood [11].

In stochastic maximum-flow interdiction, both arc capacities and the success of interdiction attempts can be random. The leader can (attempt to) reduce the capacity of a subset of arcs, possibly to zero. The follower maximizes flow in the residual network, realizing the arc capacities. The leader’s goal is to minimize the expected value of the resulting maximum flow. Both Cormican *et al.* [12] and Janjarassuk and Linderoth [13] consider interdiction of a stochastic maximum-flow network in which the sample space is large—even infinite, because, for example, arc capacities are continuous random variables. Cormican *et al.* use deterministically valid upper and lower bounds on the optimal value, that is, on the minimal value of the expected maximum flow. These bounds are defined on a partition of the sample space, which is iteratively refined, tightening the bounds. Janjarassuk and Linderoth instead form upper and lower bounds on the optimal value using Monte Carlo sampling. While it is beyond the scope of this article, these types

of bounds can also be used in the stochastic network interdiction problems that we consider here when the sample space is large.

DETERMINISTIC SHORTEST-PATH NETWORK INTERDICTION

Formulation and Reformulation

In our shortest-path interdiction model, the timing of the decisions and the information available to the two adversaries are as follows. The adversaries agree on the network topology $G(N, A)$, the follower’s source, $s \in N$, and terminus, $t \in N$, and they further agree on the network’s arc lengths. The leader knows the mechanism by which the follower selects an s - t path, that is, that the follower selects a shortest path. Decisions are made sequentially. The leader first lengthens some subset of the network’s arcs. The follower then selects a shortest s - t path, knowing which arcs were lengthened. The leader’s goal is to maximize the length of the follower’s shortest path. We formulate the deterministic shortest-path network interdiction model as follows:

Network and sets:

$G(N, A)$ = directed network with nodes N
and arcs A
 $FS(i)$ = set of arcs leaving node i
 $RS(i)$ = set of arcs entering node i

Data:

R = resource matrix limiting interdiction decisions
 r = resource vector limiting interdiction decisions
 c_{ij} = original length of arc $(i, j) \in A$; $c_{ij} > 0$
 d_{ij} = additional length if arc $(i, j) \in A$ is interdicted; $d_{ij} > 0$

Leader’s decision variables:

$x_{ij} = 1$ if arc $(i, j) \in A$ is lengthened and 0 otherwise

Follower’s decision variables:

$y_{ij} = 1$ if arc $(i, j) \in A$ is traversed in follower’s shortest path and 0 otherwise

Deterministic Shortest-Path Interdiction Formulation:

$$z^* = \max_{x \in X} \left[\begin{array}{l} \min_y \sum_{(i,j) \in A} (c_{ij} + d_{ij}x_{ij})y_{ij} \\ \text{s.t.} \sum_{(i,j) \in FS(i)} y_{ij} - \sum_{(j,i) \in RS(i)} y_{ji} \\ = \begin{cases} 1 & i = s \\ 0 & i \in N \setminus \{s, t\} \\ -1 & i = t \end{cases} \\ y_{ij} \geq 0, (i,j) \in A \end{array} \right], \quad (1)$$

where $X = \{x : Rx \leq r, x \in \{0, 1\}^{|A|}\}$. Here, x and y denote the $|A|$ -dimensional binary vectors with respective components x_{ij} and y_{ij} , $(i, j) \in A$. We assume that G has an s - t path. The set X can, for example, simply constrain the number of arcs the leader can lengthen by setting $R = (1, 1, \dots, 1)$, $x \in X$ can represent multiple knapsack constraints across different interdiction resources, and/or X can incorporate more general constraints. The leader may be precluded from interdicting certain arcs by the choice of R and r , and X can also include logical inequalities to exclude nonoptimal combinations of interdictions [14].

With $x \in X$ fixed, the inner optimization problem in model (1) is simply the follower's shortest-path problem, formulated as a minimum-cost flow problem, with one unit of flow originating at s and terminating at t . Arc (i, j) has length c_{ij} if $x_{ij} = 0$ and $c_{ij} + d_{ij}$ if $x_{ij} = 1$.

Owing to its max-min structure, model (1) does not lend itself to direct solution by a general purpose solver for MIPs. However, the inner problem is an LP and so we can (i) fix $x \in X$, (ii) take the dual of the inner LP, and (iii) release x . With $-\pi_i$, $i \in N$, denoting the dual variables associated with the flow-balance constraints of model (1), doing so leads to the following MIP:

$$z^* = \max_{x, \pi} \pi_t \quad (2a)$$

$$\text{s.t. } x \in X \quad (2b)$$

$$\pi_j - \pi_i - d_{ij}x_{ij} \leq c_{ij}, (i, j) \in A \quad (2c)$$

$$\pi_s = 0. \quad (2d)$$

When x is fixed we have the dual of a shortest-path problem, with π_i , $i \in N$,

denoting the length of the shortest path from s to i , here with arc lengths in the interdicted network as dictated by x . Constraint (2c), coupled with maximization of the objective function, captures Bellman's equations for the shortest-path problem

$$\pi_j = \min_{i \in RS(j)} \{\pi_i + (c_{ij} + d_{ij}x_{ij})\} \forall j \in N.$$

Having expressed our model as a single, nonnested, optimization problem, we can attempt to solve model (2) using a branch-and-bound algorithm for general MIPs. This approach may succeed, and if so, is arguably the simplest way to solve model (1). However, one reason this approach may fail is that the LP relaxation of model (2) can be weak, especially when the values of the d_{ij} parameters are large relative to the original arc lengths, c_{ij} . Roughly speaking, this weakness arises because the LP solution's fractional values of x are such that the set of attractive paths for the follower have equal length. Valid inequalities have been proposed to tighten the LP relaxation and we discuss these further below.

Remarks.

1. Model (1) captures discrete interdiction of arcs, but if we relax the binary constraints on x to $0 \leq x_{ij} \leq 1$, $(i, j) \in A$, then we allow continuous lengthening of arc (i, j) from c_{ij} up to $c_{ij} + d_{ij}$ as considered by Fulkerson and Harding [15] and Golden [16]. In this case, we can solve the desired interdiction model by solving the LP relaxation of model (2).
2. Model (1) is a bilevel Stackelberg game with the leader's decision transparent to the follower. An alternative that instead captures secrecy is a Cournot game in which the adversaries effectively announce their decisions simultaneously. In our setting, this leads to a two-person zero-sum game involving so-called *mixed strategies*. Player II (formerly the follower) places a probability distribution on an exponentially large collection of s - t paths, and Player I (formerly the leader) places a probability distribution on the exponentially

large collection of feasible solutions of X . See Washburn and Wood [17] for such a model and Nehme [18] for a hybrid model in which some of the leader's decisions are transparent to the follower but others are concealed.

3. We assume above that the leader and follower agree on the arc lengths. An alternative is to model the two adversaries as having differing perceptions of the arc lengths. Bayrak and Bailey [19] study shortest-path network interdiction under such information asymmetries.
4. Exchanging the order of the decisions in model (1) to form " $\min_y \max_x$ " yields the robust optimization model of Bertsimas and Sim [20], where the decision-maker (the leader) first selects an s - t path under *uncertain* arc lengths. Their model of uncertainty is adversarial, with nature (the follower) lengthening arcs in a worst-case manner, given y 's s - t path and constrained by X . In the interdiction model (1), the path-selection decision is made in a *certain* environment. That said, model (1) can provide insight regarding vulnerabilities in a system we operate by allowing a resource-constrained adversary to optimally disrupt our system. Presumably, we seek to understand such vulnerabilities so that we can harden our system prior to the potential disruption.
5. The special case in which $X = \{x : \sum_{(i,j) \in A} x_{ij} \leq k\}$ and d_{ij} is sufficiently large for all $(i,j) \in A$, leads to a cardinality-constrained shortest-path interdiction problem in which interdiction of an arc effectively removes it from the network. This problem is known as the *k-most-vital arcs problem* [21,22] and the associated decision problem is strongly NP-complete [23,24].
6. We assume that the leader knows the follower will select a shortest s - t path. If the leader is unsure how the follower will behave, then model (1) is arguably appropriately conservative, that is, it

plans for the worst case. If it is known, for example, that the follower will select a random s - t path, or traverse the network according to a Markov decision process (MDP), then a different interdiction model may be in order, depending on the leader's goal. We return briefly to a random-walk model in the next section. See Bailey *et al.* [25] for interdiction of a follower who solves an MDP.

7. Model (1) can be used to interdict a follower who selects a maximum-reliability s - t path in a network in which each arc has some probability of evading detection and a reduced probability of evading detection when a sensor is installed on the arc. We return to this in greater detail in the section titled "Interdicting a Maximum-Reliability Path: Known s - t Pair."

Algorithms

We can employ Benders' decomposition [26] to solve model (2). Here, we partition the decision variables into binary variables, x , and continuous variables, π . We can view model (2) as

$$z^* = \max_{x \in X} h(x), \quad (3)$$

where

$$\begin{aligned} h(x) &= \max_{\pi} \pi_t \\ \text{s.t. } & \pi_j - \pi_i \leq c_{ij} + d_{ij}x_{ij}, (i,j) \in A \\ & \pi_s = 0 \\ & = \min_y \sum_{(i,j) \in A} (c_{ij} + d_{ij}x_{ij})y_{ij} \end{aligned} \quad (4a)$$

$$\begin{aligned} \text{s.t. } & \sum_{(i,j) \in FS(i)} y_{ij} - \sum_{(j,i) \in RS(i)} y_{ji} \\ & = \begin{cases} 1 & i = s \\ 0 & i \in N \setminus \{s, t\} \\ -1 & i = t \end{cases} \end{aligned} \quad (4b)$$

$$y_{ij} \geq 0, (i,j) \in A, \quad (4c)$$

and where the first linear program, with optimal value $h(x)$, is again dual to that defined in model (4).

The function $h(\cdot)$ is concave on the convex hull of X . Benders' decomposition iteratively builds a piecewise-linear outer approximation of $h(\cdot)$ as follows. Let Y denote the feasible region of model (4) and let $y^{(\ell)}$, $\ell \in \mathcal{L}$, denote all of Y 's extreme points, that is, each $y^{(\ell)}$ denotes an s - t path that the follower can select. Denote these paths $P^{(\ell)}$, $\ell \in \mathcal{L}$, that is, $(i, j) \in P^{(\ell)}$ if and only if $y_{ij}^{(\ell)} = 1$. The so-called *full master program* for Benders' decomposition is then

$$\begin{aligned} z^* = \max_{x, \theta} \quad & \theta \\ \text{s.t.} \quad & \theta \leq \sum_{(i,j) \in A} (c_{ij} + d_{ij}x_{ij})y_{ij}^{(\ell)}, \quad \ell \in \mathcal{L} \\ & x \in X, \end{aligned}$$

where the inequalities defining θ are known as optimality cuts, or simply cuts. Equivalently, using our path notation, we can write the full master program as

$$\begin{aligned} z^* = \max_{x, \theta} \quad & \theta \\ \text{s.t.} \quad & \theta \leq \sum_{(i,j) \in P^{(\ell)}} (c_{ij} + d_{ij}x_{ij}), \quad \ell \in \mathcal{L} \\ & x \in X. \end{aligned} \tag{5}$$

Algorithm 1. Benders' decomposition algorithm for model (1).

Input: an instance of model (1), error tolerance $\epsilon \geq 0$

Output: interdiction plan $\bar{x}$ with $z^* - h(\bar{x}) \leq \epsilon$

find at least one s - t path; initialize L and program (6)'s set of cuts

$\underline{z} \leftarrow 0$

repeat

 solve model (6) to obtain $\hat{x}$ and $\bar{z}$

 solve model (4) with $x = \hat{x}$ to obtain s - t path P and optimal value $h(\hat{x})$

 update L and model (6)'s set of cuts with path P

if $h(\hat{x}) > \underline{z}$ **then**

$\bar{x} \leftarrow \hat{x}$; $\underline{z} \leftarrow h(\hat{x})$

end if

until $(\bar{z} - \underline{z} \leq \epsilon)$

return $\bar{x}$ and $\underline{z} = h(\bar{x})$

Israeli and Wood [9] report that direct application of Algorithm 1 is ineffective in solving model (1). It is more effective to simply apply a general purpose MIP solver to formulation (2). We detail Benders' decomposition for two reasons. First, Israeli and Wood [9] report that a version of Algorithm 1 is quite effective when enhanced

In this way, the full master program (5) is an "obviously correct" formulation that we could have written down immediately following the problem description. (This is arguably not the case for all applications of Benders' decomposition.)

Of course, enumerating all s - t paths is out of the question for all but the smallest of networks. Benders' decomposition, also known as the *L-shaped method* [27], iteratively updates a subset of paths $L \subset \mathcal{L}$ in a relaxed master program

$$\begin{aligned} \bar{z} = \max_{x, \theta} \quad & \theta \\ \text{s.t.} \quad & \theta \leq \sum_{(i,j) \in P^{(\ell)}} (c_{ij} + d_{ij}x_{ij}), \quad \ell \in L \\ & x \in X. \end{aligned} \tag{6}$$

In particular, we solve the master program (6) to obtain an interdiction plan $\bar{x}$ and an optimal value satisfying $\bar{z} \geq z^*$. We then solve the shortest-path problem (4) with $x = \bar{x}$ to obtain a new path P with optimal value $h(\bar{x}) \leq z^*$. If $\bar{z} - h(\bar{x})$ is sufficiently small, we terminate. Otherwise, we add P to the collection of paths indexed by L and repeat. This is formalized in Algorithm 1.

in a manner we describe shortly. Second, in the stochastic case, even when Benders' decomposition is not enhanced, it is more effective than attempting to solve directly the stochastic analog of model (2).

Solving the MIP master program (6) at each iteration requires much more computational effort than solving the

shortest-path subproblem (4). Israeli and Wood [9] find that enumerating *all* shortest s - t paths when solving model (4) for a fixed x , or even enumerating near-shortest paths, and adding the associated collection of cuts to model (6) improves performance.

We now turn to an idea that can be used on its own or, better, to enhance Algorithm 1. Suppose that P is a path associated with a cut of model (6) and suppose the lower bound of Algorithm 1 satisfies $\underline{z} > \sum_{(i,j) \in P} c_{ij}$. Then, we may add a path-covering inequality

$$\sum_{(i,j) \in P} x_{ij} \geq 1, \quad (7)$$

to the relaxed master program. The intuition behind inequality (7) is simple: The leader has, in the course of the algorithm, already forced the follower to a path with length $\underline{z}$. If not interdicted, path P has length $\sum_{(i,j) \in P} c_{ij} < \underline{z}$. So, the leader must interdict at least one arc on P , as enforced by inequality (7).

This idea can be pushed further. Suppose that P is a path associated with a cut of model (6) and suppose the lower bound of Algorithm 1 satisfies $\underline{z} > \sum_{(i,j) \in P} c_{ij} + \max_{(i,j) \in P} d_{ij}$. Then, we may add

$$\sum_{(i,j) \in P} x_{ij} \geq 2, \quad (8)$$

and so on.

To simplify the discussion, we now assume that (i) an interdicted arc is removed from the network and (ii) there is an s - t path in the residual network for all $x \in X$, that is, it is impossible to disconnect s and t . While arc

removal can be handled in our original formulation by selecting d_{ij} to be sufficiently large, this can lead to very weak LP relaxations, and hence, we seek another approach. Moreover, the assumption that interdiction removes an arc is without loss of generality because an arc (i,j) can be replaced by two arcs in parallel (albeit with appropriate extensions of notation): one arc from i to j has length c_{ij} , the second arc from i to j has length $c_{ij} + d_{ij}$, and we disallow interdiction of the latter arc through constraints $x \in X$.

We can partition $\mathcal{L}$ via $\mathcal{L} = \underline{\mathcal{L}} \cup \mathcal{L}^* \cup \bar{\mathcal{L}}$, where

$$\begin{aligned} \underline{\mathcal{L}} &= \left\{ \ell : \sum_{(i,j) \in P^{(\ell)}} c_{ij} < z^* \right\} \\ \mathcal{L}^* &= \left\{ \ell : \sum_{(i,j) \in P^{(\ell)}} c_{ij} = z^* \right\} \\ \bar{\mathcal{L}} &= \left\{ \ell : \sum_{(i,j) \in P^{(\ell)}} c_{ij} > z^* \right\}. \end{aligned}$$

Consider

$$x \in X, \quad \sum_{(i,j) \in P^{(\ell)}} x_{ij} \geq 1, \quad \ell \in L. \quad (9)$$

An interdiction plan x satisfies system (9) with $L = \underline{\mathcal{L}}$ if and only if x solves model (1). Moreover, system (9) with $L = \underline{\mathcal{L}} \cup \mathcal{L}^*$ is infeasible. Of course, we do not know z^* and hence cannot partition $\mathcal{L}$ *a priori*, but we can do so algorithmically as detailed in Algorithm 2.

Algorithm 2. Covering-based decomposition algorithm for model (1).

Input: an instance of model (1)

Output: optimal solution x^* and optimal value z^* to model (1)

$L \leftarrow \emptyset$

$\hat{x} \leftarrow 0$

$\underline{z} \leftarrow 0$

repeat

 solve model (4) with $x = \hat{x}$ to obtain s - t path P and optimal value $h(\hat{x})$

 update L and system (9)'s set of inequalities with path P

if $h(\hat{x}) > \underline{z}$ **then**

```

 $\bar{x} \leftarrow \hat{x}; \bar{z} \leftarrow h(\hat{x})$ 
end if
  find  $\hat{x}$  satisfying system (9) or determine that system (9) is infeasible
until (system (9) is infeasible)
return  $x^* = \bar{x}$  and  $z^* = \bar{z}$ 

```

An attractive aspect of Algorithm 2 is that we repeatedly solve the “covering problem,” system (9), which tends to be much easier to solve than the relaxed master program (6) of Algorithm 1. On the other hand, Algorithm 2 tends to require more iterations than Algorithm 1. Moreover, Algorithm 2 does not have an upper bound that can be used to terminate with an ϵ -optimal solution. We note that inequalities (7) and (8) are not standard valid inequalities. Rather, they are guaranteed not to cut off all optimal solutions unless one has already been found and are termed supervalid inequalities [9]. While we do not detail it here, Israeli and Wood [9] describe an effective algorithm for solving model (1) that combines the key ideas of Algorithms 1 and 2.

STOCHASTIC SHORTEST-PATH NETWORK INTERDICTION

In this section, we generalize the deterministic interdiction model (1) to the stochastic setting. The source-terminus pair and the arc lengths that the follower faces are uncertain to the leader. Let $\xi = (c, d, s, t)$ denote these uncertain elements, and let $\omega \in \Omega$ index a finite set of realizations, $\xi^\omega = (c^\omega, d^\omega, s^\omega, t^\omega)$, that are assumed known to the leader only through a probability mass function, ϕ^ω , $\omega \in \Omega$. We assume that Ω is of modest size. The timing of the decisions and realizations of the uncertainty are as follows. First, the leader interdicts some subset of arcs via $x \in X$. Then, a source-terminus pair and arc lengths are revealed, $\xi^\omega = (c^\omega, d^\omega, s^\omega, t^\omega)$. The follower solves what is now a deterministic problem to select a shortest s^ω - t^ω path, knowing the source, terminus, and the arc lengths dictated by ω and $x \in X$.

We formalize this generalization by extending model (3) to this stochastic setting

$$z^* = \max_{x \in X} \sum_{\omega \in \Omega} \phi^\omega h(x, \xi^\omega), \quad (10)$$

where we have also extended the definition of $h(\cdot)$ to

$$\begin{aligned}
 h(x, \xi^\omega) &= \min_y \sum_{(i,j) \in A} (c_{ij}^\omega + d_{ij}^\omega x_{ij}) y_{ij} \\
 \text{s.t.} \quad &\sum_{(i,j) \in FS(i)} y_{ij} - \sum_{(j,i) \in RS(i)} y_{ji} \\
 &= \begin{cases} 1 & i = s^\omega \\ 0 & i \in N \setminus \{s^\omega, t^\omega\} \\ -1 & i = t^\omega \end{cases} \quad (11) \\
 &y_{ij} \geq 0, (i,j) \in A.
 \end{aligned}$$

Parallel to our development above, we can reformulate model (10) as a large-scale MIP,

$$\begin{aligned}
 z^* &= \max_{x, \pi} \sum_{\omega \in \Omega} \phi^\omega \pi_{t^\omega}^\omega \\
 \text{s.t.} \quad &x \in X \\
 &\pi_j^\omega - \pi_i^\omega - d_{ij}^\omega x_{ij} \leq c_{ij}^\omega, \\
 &\quad (i,j) \in A, \omega \in \Omega \\
 &\pi_{s^\omega}^\omega = 0, \omega \in \Omega,
 \end{aligned} \quad (12)$$

and attempt to solve model (12) directly using an MIP solver.

The same potential shortcomings that we describe above apply to direct solution of model (12) and so we extend Algorithm 1 to the stochastic setting. The master program is

$$\begin{aligned}
 \max_{x, \theta} \quad &\sum_{\omega \in \Omega} \phi^\omega \theta^\omega \\
 \text{s.t.} \quad &\theta^\omega \leq \sum_{(i,j) \in P(\ell, \omega)} (c_{ij}^\omega + d_{ij}^\omega x_{ij}), \\
 &\ell \in L^\omega, \quad \omega \in \Omega \\
 &x \in X.
 \end{aligned} \quad (13)$$

Extending our notation from the previous section, $P^{(\ell, \omega)}$, $\ell \in L^\omega$, denotes all of the s^ω - t^ω paths, $\omega \in \Omega$. If $L^\omega = L^\omega$, then model (13) is the full master program that is equivalent to model (10) with optimal value z^* . If $L^\omega \subset L^\omega$,

$\omega \in \Omega$, then model (13) has only a subset of the cut constraints and is a relaxed master program, whose optimal value we denote $\bar{z}$. Algorithm 3 iteratively grows the sets L^ω

by alternately solving model (13) to obtain $\bar{x}$ and solving the collection of shortest-path problems (11) indexed by $\omega \in \Omega$ with $x = \bar{x}$.

Algorithm 3. Benders' decomposition algorithm for model (10).

Input: an instance of model (10), error tolerance $\epsilon \geq 0$
Output: interdiction plan $\bar{x}$ with $z^* - \sum_{\omega \in \Omega} \phi^\omega h(\bar{x}, \xi^\omega) \leq \epsilon$

for $\omega \in \Omega$ **do**
 find at least one s^ω - t^ω path; initialize L^ω and program (13)'s set of cuts
end for
 $\underline{z} \leftarrow 0$
repeat
 solve model (13) to obtain $\hat{x}$ and $\bar{z}$
 for $\omega \in \Omega$
 solve model (11) with $x = \hat{x}$ to obtain s^ω - t^ω path P^ω and $h(\hat{x}, \xi^\omega)$
 update L^ω and model (13)'s set of cuts with path P^ω
 end for
 if $\sum_{\omega \in \Omega} \phi^\omega h(\hat{x}, \xi^\omega) > \underline{z}$ **then**
 $\bar{x} \leftarrow \hat{x}$; $\underline{z} \leftarrow \sum_{\omega \in \Omega} \phi^\omega h(\hat{x}, \xi^\omega)$
 end if
until $(\bar{z} - \underline{z} \leq \epsilon)$
return $\bar{x}$ and $\underline{z} = \sum_{\omega \in \Omega} \phi^\omega h(\bar{x}, \xi^\omega)$

Pan and Morton [28] report that Algorithm 3 outperforms direct application of an MIP solver to a variant of model (12). This contrasts with the situation in the deterministic setting because of the stochastic nature of the problem. Specifically, when x is fixed we can solve model (12) by solving $|\Omega|$ separate shortest-path problems. Consistent with application of the decomposition algorithm to the deterministic problem, Pan and Morton [28] find that valid inequalities and generating multiple cuts (for each ω) at each iteration can significantly improve the decomposition algorithm's performance. When we do not employ the valid inequalities that we discuss next, the linear-programming relaxation of the master program can be weak, precluding solution of all but the smallest of problem instances.

For simplicity, we again assume that interdiction of an arc amounts to effectively removing that arc from the network, and that there is an s^ω - t^ω path for all $\omega \in \Omega$ and $x \in X$. Let h_ℓ^ω be the length of the path associated with cut constraint $\ell \in L^\omega$ in master program (13) at some iteration of Algorithm 3. Let $T^\omega = \{\ell_1, \ell_2, \dots, \ell_k\} \subset L^\omega$,

where these indices satisfy the ordering

$$\min_{\ell \in L^\omega} h_\ell^\omega = h_{\ell_1}^\omega \leq h_{\ell_2}^\omega \leq \dots \leq h_{\ell_k}^\omega \leq h_{\ell_{k+1}}^\omega \equiv \bar{z}^\omega, \quad (14)$$

where $\bar{z}^\omega$ is an upper bound on the length of follower ω 's shortest path under an optimal interdiction plan. A *step inequality* is of the following form

$$\theta^\omega \leq h_{\ell_1}^\omega + \underbrace{(h_{\ell_2}^\omega - h_{\ell_1}^\omega)v_{\ell_1}^\omega + (h_{\ell_3}^\omega - h_{\ell_2}^\omega)v_{\ell_2}^\omega + \dots + (h_{\ell_{k+1}}^\omega - h_{\ell_k}^\omega)v_{\ell_k}^\omega}_{\sum_{\ell_i \in T^\omega} (h_{\ell_{i+1}}^\omega - h_{\ell_i}^\omega)v_{\ell_i}^\omega}, \quad (15)$$

where

$$v_\ell^\omega \leq \sum_{(i,j) \in P^{(\ell,\omega)}} x_{ij}, \ell \in T^\omega \quad (16a)$$

$$0 \leq v_\ell^\omega \leq 1, \ell \in T^\omega. \quad (16b)$$

Consider path $P^{(\ell_1,\omega)}$, that is, follower ω 's shortest path (among the paths in L^ω), which has length $h_{\ell_1}^\omega$. The idea of the step inequality

is that if the leader fails to interdict at least one arc on $P^{(\ell_1, \omega)}$ then the follower's path will have length $\theta^\omega = h_{\ell_1}^\omega$. If at least one arc on $P^{(\ell_1, \omega)}$ is interdicted, then θ^ω telescopes to $h_{\ell_2}^\omega$, unless an arc on $P^{(\ell_2, \omega)}$ is also interdicted, and so on.

Given a solution to the LP relaxation of model (13), we can efficiently identify the most violated step inequality for each $\omega \in \Omega$. This amounts to finding the index set $T^\omega \subset L^\omega$ that minimizes the right-hand side of inequality (15) with x , and hence v via inequality (16a), fixed. This can be accomplished by solving a separation problem involving a shortest-path problem on an acyclic network whose nodes correspond to elements of L^ω [28]. Addition of the step inequalities can dramatically tighten the LP relaxation of model (13) and reduce the running time of Algorithm 3 [28]. Step inequalities still apply when we relax the assumption that an interdicted arc is removed from the network. In this case, we must replace the index set, $P^{(\ell, \omega)}$, on the right-hand side of inequality (16a) with the set of uninterdicted arcs on $P^{(\ell, \omega)}$.

Remarks.

1. That (s^ω, t^ω) , $\omega \in \Omega$, is assumed to follow a probability distribution is an important *modeling* choice. It contrasts sharply with the way we model the follower selecting a path in the network. Instead of the worst-case path-selection model that we consider, the follower could instead take a random walk from source to terminus [29,30]. So, we can conceive four different interdiction models based on whether the follower selects a source-terminus pair and a path, respectively, in a worst-case or random manner.
2. Randomness in d_{ij} can model uncertainty in the leader's ability to lengthen arc (i, j) . For example, d_{ij} can be a binary random variable in which an interdiction can fail, and d_{ij} takes value zero, or succeed, and d_{ij} takes some lengthening value. Such models of stochastic binary effectiveness of

interdiction attempts in maximum-flow interdiction have also been developed [12,13].

3. Algorithm 3 is a multicut version of Benders' decomposition. A single-cut variant, in which cuts are aggregated across $\omega \in \Omega$, has a smaller master program with fewer cut constraints and fewer decision variables. But, the single-cut algorithm typically requires more iterations than its multicut counterpart. For more on multicut and single-cut algorithms, see Birge and Louveaux [31].
4. In implementing Algorithm 3, when we update L^ω and program (13)'s set of cuts, we should ensure that we do not add a redundant cut. In general, this can be done by seeing whether the current pair (x, θ^ω) obtained when solving model (13), is "cut off," that is, violates, the proposed cut. However, in the current setting, it is perhaps preferable to simply ensure that the associated path P^ω is indeed new.
5. The path-covering inequalities (7) used in the deterministic case differ from the step inequalities (15) and (16) we describe here. That said, both share the key idea of conditioning on whether at least one arc on an attractive path for the follower is interdicted and are related to the star inequalities of Atamtürk *et al.* [32].

INTERDICTING A MAXIMUM-RELIABILITY PATH: KNOWN s - t PAIR

Suppose the follower seeks an s - t path in G that maximizes the probability of evading detection. If the follower traverses arc $(i, j) \in A$, the probability of evading detection on that arc, by the leader's *indigenous* sensing capability, is p_{ij} . The leader can augment the indigenous capability by interdicting that arc, that is, installing a sensor on $(i, j) \in A$, and reducing the evasion probability to q_{ij} , where $0 < q_{ij} < p_{ij} \leq 1$. Assuming detection events on distinct arcs in the network are mutually independent, and that the leader's sensors are transparent to the follower, we

can formulate this interdiction model as

$$\min_{x \in X} \left[\begin{array}{ll} \max_P & \prod_{(i,j) \in P} [p_{ij}(1-x_{ij}) + q_{ij}x_{ij}] \\ \text{s.t.} & P \text{ is an } s\text{-}t \text{ path} \end{array} \right]. \quad (17)$$

The notation in model (17) is identical to that developed above with the addition of the evasion probabilities p_{ij} and q_{ij} just introduced and the fact that the inner maximization over P is over all s - t paths. Carrying out a standard logarithmic transformation [33] we obtain the following objective function:

$$\begin{aligned} & \ln \left(\prod_{(i,j) \in P} [p_{ij}(1-x_{ij}) + q_{ij}x_{ij}] \right) \\ &= \sum_{(i,j) \in P} \ln [p_{ij}(1-x_{ij}) + q_{ij}x_{ij}] \\ &= \sum_{(i,j) \in P} [\ln(p_{ij})(1-x_{ij}) + \ln(q_{ij})x_{ij}] \\ &= \sum_{(i,j) \in P} [\ln(p_{ij}) + \ln(q_{ij}/p_{ij})x_{ij}], \end{aligned}$$

where the second inequality holds only because x_{ij} is binary.

So, model (17) is equivalent to

$$\min_{x \in X} \left[\begin{array}{ll} \max_y & \sum_{(i,j) \in A} [\ln(p_{ij}) + \ln(q_{ij}/p_{ij})x_{ij}] y_{ij} \\ \text{s.t.} & \sum_{(i,j) \in FS(i)} y_{ij} - \sum_{(j,i) \in RS(i)} y_{ji} \\ &= \begin{cases} 1 & i = s \\ 0 & i \in N \setminus \{s, t\} \\ -1 & i = t \end{cases} \\ & y_{ij} \geq 0, (i,j) \in A \end{array} \right]. \quad (18)$$

Model (18), in turn, is equivalent to model (1), with $\max_x \min_y$, where $c_{ij} = -\ln(p_{ij})$ and $d_{ij} = -\ln(q_{ij}/p_{ij})$.

INTERDICTION A MAXIMUM-RELIABILITY PATH: STOCHASTIC s - t PAIR

The previous section shows that interdicting a maximum-reliability path with a known s - t pair can be captured by our deterministic shortest-path interdiction model (1). It

is natural to then hope that interdicting a maximum-reliability path, where s - t is uncertain but governed by a known probability mass function, can be captured by our stochastic shortest-path interdiction model (1). Unfortunately, as we see shortly, another modeling approach is required in the case of a stochastic s - t pair.

Analogous to our development in the section titled “Stochastic Shortest-Path Network Interdiction,” let $\xi = (p, q, s, t)$ denote the uncertain elements and let $\omega \in \Omega$ index a finite set of realizations, $\xi^\omega = (p^\omega, q^\omega, s^\omega, t^\omega)$, known to the leader only through a probability mass function, ϕ^ω , $\omega \in \Omega$. First, the leader installs sensors on a subset of arcs via $x \in X$. Then, a source-terminus pair and evasion probabilities are revealed, $\xi^\omega = (p^\omega, q^\omega, s^\omega, t^\omega)$. The follower solves what is now a deterministic problem to select an s^ω - t^ω path with maximum evasion probability, knowing the source, terminus, and per-arc evasion probabilities as dictated by ω and by the locations of the sensors, x .

We formulate this generalization as

$$\min_{x \in X} \sum_{\omega \in \Omega} \phi^\omega h(x, \xi^\omega), \quad (19)$$

where we now define

$$\begin{aligned} h(x, \xi^\omega) &= \max_P \prod_{(i,j) \in P} [p_{ij}^\omega(1-x_{ij}) + q_{ij}^\omega x_{ij}] \\ \text{s.t. } & P \text{ is an } s^\omega\text{-}t^\omega \text{ path.} \end{aligned} \quad (20)$$

Here, $h(x, \xi^\omega)$ is the follower’s *conditional* evasion probability, conditioned on ξ^ω . Hence, the objective function in model (19) is the (unconditional) probability the follower evades detection, and that is what the leader minimizes.

When $|\Omega| = 1$ we know that model (19) is equivalent to model (1) via the logarithmic transformation described in the previous section. Unfortunately, this fails when $|\Omega| > 1$. In other words, we cannot replace model (20) with the inner maximization in model (18), at least when trying to solve model (19). In short, the reason is that for positive functions, while $\min_x f(x)$ is equivalent to $\min_x \ln(f(x))$, $\min_x [f_1(x) + f_2(x)]$ is *not* equivalent to $\min_x [\ln(f_1(x)) + \ln(f_2(x))]$.

The following model is equivalent to model (19):

$$\min_{x \in X} \sum_{\omega \in \Omega} \phi^\omega \exp[\ln(h(x, \xi^\omega))]. \quad (21)$$

And, $h(x, \xi^\omega)$ can be represented by a shortest-(or rather longest-) path formulation, as in the inner maximization in model (18), or via its dual. Using the latter, the following is the analog of model (12) for interdicting a stochastic maximum-reliability path

$$\begin{aligned} z^* = \min_{x, \pi} \quad & \sum_{\omega \in \Omega} \phi^\omega e^{\pi t^\omega} \\ \text{s.t.} \quad & x \in X \\ & \pi_j^\omega - \pi_i^\omega - \ln(q_{ij}^\omega/p_{ij}^\omega)x_{ij} \\ & \geq \ln(p_{ij}^\omega), (i, j) \in A, \omega \in \Omega \\ & \pi_{s^\omega}^\omega = 0, \omega \in \Omega. \end{aligned} \quad (22)$$

Model (22) is a nonlinear MIP. Its continuous relaxation is a convex nonlinear program, and so it may be computationally tractable. Still, we much prefer a linear MIP, and so we pursue another approach.

In a *generalized* network-flow model, flow on an arc can experience a gain or loss. If an arc's gain factor is 0.9 and 0.8 units of flow are initiated at that arc's tail, then 0.72 units depart its head. The following recasting of $h(\cdot)$, as defined in model (20), uses this idea:

$$\begin{aligned} h(x, \xi^\omega) \\ = \max_{y, z} y_{t^\omega} \end{aligned} \quad (23a)$$

$$\text{s.t.} \quad \sum_{(i, j) \in FS(s^\omega)} (y_{ij} + z_{ij}) = 1 \quad (23b)$$

$$\begin{aligned} \sum_{(i, j) \in FS(i)} (y_{ij} + z_{ij}) - \sum_{(j, i) \in RS(i)} (p_{ji}^\omega y_{ji} + q_{ji}^\omega z_{ji}) = 0, \\ i \in N \setminus \{s^\omega, t^\omega\} \end{aligned} \quad (23c)$$

$$y_{t^\omega} - \sum_{(j, i) \in RS(t^\omega)} (p_{ji}^\omega y_{ji} + q_{ji}^\omega z_{ji}) = 0 \quad (23d)$$

$$0 \leq y_{ij} \leq 1 - x_{ij}, \quad (i, j) \in A \quad (23e)$$

$$0 \leq z_{ij} \leq x_{ij}, \quad (i, j) \in A. \quad (23f)$$

We view each arc that can receive a sensor as two arcs in parallel, and if $x_{ij} = 1$ then flow may occur only on the “sensor” arc via z_{ij} , and otherwise only on the “no sensor” arc via y_{ij} . Flow on arc (i, j) is multiplied by that arc's gain factor, either p_{ij}^ω or q_{ij}^ω . Constraint (23b) forces one unit of flow out of s^ω , flow is conserved at all intermediate nodes in constraint (23c), and constraint (23d) defines the flow that reaches t^ω as y_{t^ω} . That value is maximized in the objective function (23a). Flow occurs on the appropriate arc due to the leader's decision variable x_{ij} in constraints (23e) and (23f). We note that the upper bound in the latter constraint can be dropped since $p_{ij}^\omega > q_{ij}^\omega$.

Model (19) with h defined in model (23) now has a linear subproblem but is in min-max form. We have dealt with this in the sections above by taking the dual of the inner linear program. Attempting to do so here leads to a new complication. Namely, the resulting model is *not* a linear MIP because dual variables on constraint (23e) multiply x_{ij} . The latter variables are binary and hence these nonlinear terms can be linearized [6]. That said, we view what follows as a more attractive approach, rooted in an exact-penalty result [34, Lemma 2]:

Theorem 1. *Suppose the following linear program has a finite optimal solution:*

$$\begin{aligned} h(x) = \max_y \quad & fy \\ \text{s.t.} \quad & Dy \leq d \\ & 0 \leq y \leq U(e - x) : \pi(x). \end{aligned} \quad (24)$$

Here, e is the vector of all ones, $U = \text{diag}(u)$, where $u = (u_1, \dots, u_n)$, and the domain of h is $X = \{x : Rx \leq r, x \in \{0, 1\}^n\}$. Assume $\bar{\pi}$ satisfies $\bar{\pi} \geq \pi^*(x)$, for all $x \in X$, where $\pi^*(x)$ is an optimal dual (sub)vector to model (24). Let $\bar{\Pi} = \text{diag}(\bar{\pi})$ and consider

$$\begin{aligned} \bar{h}(x) = \max_y \quad & (f - x^T \bar{\Pi})y \\ \text{s.t.} \quad & Dy \leq d \\ & 0 \leq y \leq u. \end{aligned}$$

Then $h(x) = \bar{h}(x)$ for $x \in X$.

Using Theorem 1, and the fact that $p_{ij}^\omega - q_{ij}^\omega, (i,j) \in A$, provides an upper bound on optimal dual prices for constraint (23e), we can rewrite $h(\cdot)$ from model (23) as follows, with the understanding that x is restricted to X :

$$\begin{aligned}
& h(x, \xi^\omega) \\
&= \max_{y,z} y_{t^\omega} - \sum_{(i,j) \in A} (p_{ij}^\omega - q_{ij}^\omega) x_{ij} y_{ij} \\
&\text{s.t.} \quad \sum_{(i,j) \in FS(s^\omega)} (y_{ij} + z_{ij}) = 1 \\
&\quad \sum_{(i,j) \in FS(i)} (y_{ij} + z_{ij}) \\
&\quad - \sum_{(j,i) \in RS(i)} (p_{ji}^\omega y_{ji} + q_{ji}^\omega z_{ji}) \\
&\quad = 0, \quad i \in N \setminus \{s^\omega, t^\omega\} \\
&\quad y_{t^\omega} - \sum_{(j,i) \in RS(t^\omega)} (p_{ji}^\omega y_{ji} + q_{ji}^\omega z_{ji}) = 0 \\
&\quad y_{ij} \geq 0, z_{ij} \geq 0, \quad (i,j) \in A. \quad (25)
\end{aligned}$$

The constraints of model (25) differ from those of model (23) only in that the simple upper bounds in constraints (23e) and (23f) have been removed. Removal of the latter is discussed above. Removal of the former simple bound allows the follower to traverse a “no sensor” arc (y_{ij}) even if the leader installs a sensor on (i,j) via $x_{ij} = 1$. However, the follower has a new penalty in the objective function of model (25) that is sufficiently large so that there is no incentive to do so. Theorem 1 ensures that the two formulations are equivalent. The advantage of the reformulation (25) is that we can now follow the three-step process we have successfully employed before, that is, (i) fix $x \in X$, (ii) take the dual of the inner LP, and (iii) release x . Doing so leads to the following *linear* MIP:

$$\begin{aligned}
& \min_{x,\pi} \sum_{\omega \in \Omega} \phi^\omega \pi_{s^\omega}^\omega \\
& \text{s.t.} \quad x \in X \\
& \quad \pi_i^\omega - p_{ij}^\omega \pi_j^\omega + (p_{ij}^\omega - q_{ij}^\omega) x_{ij} \geq 0, \quad (i,j) \in A, \omega \in \Omega \quad (26) \\
& \quad \pi_i^\omega - q_{ij}^\omega \pi_j^\omega \geq 0, \quad (i,j) \in A, \omega \in \Omega \\
& \quad \pi_{t^\omega} = 1, \quad \omega \in \Omega.
\end{aligned}$$

The dual variables, π_i , in our shortest-path formulation (2) had the interpretation of being the length of the shortest s - i path. In model (26), the dual variables instead represent the conditional evasion probability given that the follower has successfully reached node i without being detected. If $x_{ij} = 1$ then $p_{ij}^\omega - q_{ij}^\omega$ is sufficiently large so that the first of the paired constraints in model (26) defining π_i^ω is vacuous.

While it required a bit more effort than the development in the previous sections, we have achieved a large-scale MIP formulation for interdicting a maximum-reliability path when the follower’s s - t pair is uncertain. We could go on to describe a decomposition algorithm for model (26) and to develop step inequalities for that formulation. Such a development largely parallels that of the section titled “Stochastic Shortest-Path Network Interdiction.” We do not detail it here, and instead refer the reader to Pan and Morton [28].

Remarks.

1. We could use ideas behind Kelley’s cutting-plane method [35], which is closely related to Benders’ decomposition and the L-shaped method, to construct a decomposition algorithm for the nonlinear MIP of model (22), in which the master program is a linear MIP and there are $|\Omega|$ shortest-path subproblems. However, the linear MIP of model (26) can also be decomposed using Benders’ decomposition, and its master program is at least as strong.
2. Often it may be more natural to place a sensor on a node, for example, at a security checkpoint, rather than on an arc. While alternatives are possible, this can be captured in our arc-based formulation by using a standard transformation that splits the node into two nodes and adds an arc to represent travel through the physical node.
3. Theorem 1 says that $h(x) = \bar{h}(x)$. Yet, we know $h(\cdot)$ is concave and $\bar{h}(\cdot)$ is convex on the convex hull of X . (In general, neither function is linear.) This apparent contradiction is resolved by noting

that Theorem 1 only ensures equality of h and $\bar{h}$ at binary values of x permitted by $x \in X$. The functions can differ at fractional points in the convex hull of X .

4. Pushing the previous remark further, model (19), with $h(\cdot)$ defined in model (23), involves minimization of a function that is concave on the convex hull of X . Such a function is not amenable to an outer-linearization decomposition algorithm. In contrast, model (19), with $h(\cdot)$ defined in model (25) involves minimization of a convex function on X 's convex hull, and this model lends itself to Benders' decomposition. This observation is consistent with the fact that we could directly reformulate the latter model into a single large-scale linear MIP.
5. Obtaining tight "big M " values in an integer program is key to avoiding a loose LP relaxation and hence key to computational tractability. The value $p_{ij}^\omega - q_{ij}^\omega$ in model (26) represents such a value, and it can be tightened to $\psi_j^\omega(p_{ij}^\omega - q_{ij}^\omega)$, where ψ_j^ω denotes an upper bound on the value of maximum-reliability path from j to t^ω . We can compute such a bound by finding all maximum-reliability paths for the system in which no sensors are installed. It is possible to further tighten ψ_j^ω , for example, at certain nodes in the branch-and-bound tree where some x_{ij} values have been fixed to one.

SUMMARY

We have described interdiction of shortest-path, and maximum-reliability-path, networks both with deterministic and stochastic source-terminus pairs. Duality plays a key role in reformulating a nested max-min (or, min-max) model as a nonnested MIP, at least when the leader's decision variables parameterize the objective function coefficients of the follower's model. When the leader's decision variables instead affect the right-hand side of the follower's linear

program, we made use of an exact-penalty result, along with duality, to construct an optimization model appropriate for solution by a standard MIP solver. The resulting MIP can have a weak linear-programming relaxation, and so we employed Benders' decomposition, coupled with valid inequalities, to allow solution of large-scale instances.

We have pointed to a number of variants of our interdiction model. A robust optimization model arises when we exchange the order of the optimization operators in our initial max-min model. Our model is a bilevel Stackelberg game in which the leader's decisions are transparent to the follower. When instead the leader's decisions are concealed, a two-person zero-sum Cournot game arises. We assume that the source-terminus pair is governed by a known probability mass function, but we could instead have an adversarial formulation for this model primitive. Similarly, we assume that the follower optimizes to select a worst-case path (from the leader's perspective), but we could have assumed instead that the follower takes a random walk from the source to terminus. Another model variant we pointed to represents information asymmetries between the leader and follower regarding arc lengths. Still further model variants were not touched on in this article. For example, the leader may need to prioritize, that is, rank-order, interdiction decisions because of budget uncertainty or because the leader's activities are deployed over time [18,36,37].

STOCHASTIC OPTIMAL CONTROL FORMULATIONS OF DECISION PROBLEMS

Department of Industrial and
Enterprise Systems Engineering,
University of Illinois at
Urbana-Champaign, Urbana,
Illinois

This article presents some of the most commonly used stochastic optimal control formulations. Stochastic optimal control has proved to be a valuable tool for sequential decision making under uncertainty. In fairly general terms, a stochastic optimal control problem consists of a system state equation which models the evolution of the system's trajectories under the control action in the presence of noise and a cost function which assigns a real-valued cost to the state and control trajectory over a time horizon. The time horizon associated with the optimal control problem is the interval of interest over which we need to optimize the cost function. Different formulations of the optimal control problem deal with finite, infinite, or random time horizons.

A crucial aspect of the sequential decision making problems is the fact that a greedy method of choosing a control action which minimizes present cost at each time instant may not be an optimal policy since such a choice might affect the system state so that future control actions will yield high cost. Thus, we need to balance the trade-off between finding a low present cost and the undesirability of a high future cost. The dynamic programming principle (in the section titled "Dynamic Programming," this encyclopedia) is the central idea which is used to solve such problems. Stochastic optimal control problems in discrete time are also known as *Markov decision processes*. See the section titled "Markov Decision

Processes" in this encyclopedia for further details on a discrete time formulation. We restrict ourselves to the continuous time formulations when the state evolution is the solution of a stochastic differential equation (SDE). In this case, the dynamic programming principle yields a partial differential equation which characterizes the optimal control trajectory. This partial differential equation is known as the Hamilton–Jacobi–Bellman (HJB) equation of optimal control.

The rest of the article is organized as follows: in the section titled "Preliminaries", we give a brief introduction to the mathematical setup behind the problem formulation and introduce key concepts which are useful in stating the results later. In the section titled "Formulation of the Optimal Control Problem", we give a classification of the optimal control problem in terms of the different classes of admissible control. The case of control under full state information is dealt with in the section titled "Optimal Control under Full State Information" and control under partial information is dealt with in the next section. Finally, we provide the conclusion and suggest some further reading.

PRELIMINARIES

In this section, we review some basic facts about SDEs which form the foundation of the analysis to follow. Our presentation closely follows the approach taken in Ref. 1. An SDE is an equation of the form

$$\begin{aligned}\frac{dX_t}{dt} &= b(t, X_t) + \sigma(t, X_t)W_t \\ X_t &\in \mathbb{R}^n, b(t, x) \in \mathbb{R}^n, \sigma(t, x) \in \mathbb{R}^{n \times m},\end{aligned}\quad (1)$$

where W_t is a vector whose each component is a *white noise*. An equivalent representation of the SDE is given in the following form:

$$dX_t = b(t, X_t) dt + \sigma(t, X_t) dB_t, \quad (2)$$

where B_t is an m -dimensional Brownian motion and can be heuristically interpreted as $W_t = \frac{dB_t}{dt}$. This is just a formal representation as the sample paths of B_t are nowhere differentiable. The term $b(t, x)$ is known as the *drift coefficient* and $\sigma(t, x)$ is the *diffusion coefficient*. This is known as the Itô interpretation of Equation (1). Also, a solution X_t of the SDE satisfies the integral form of the equation, that is,

$$X_t = X_0 + \int_0^t b(t, X_\tau) d\tau + \int_0^t \sigma(t, X_\tau) dB_\tau.$$

The solution X_t is known as an Itô diffusion. Let $\mathcal{F}_t = \sigma(B_s : s \leq t)$. Then X_t is known to be adapted to $\mathcal{F}_t$. The expression $I_t = \int_0^t f(\tau, \omega) dB_\tau$ is known as an *Itô integral*. It is well defined for a *predictable* or *nonanticipating* [1] stochastic process $f(t, \omega)$. The Itô integral has the following two useful properties:

1. *Martingale Property*. The integral has a continuous version and is a martingale, that is

$$\mathbb{E}(I_t | \mathcal{F}_s) = I_s, \quad s \leq t.$$

This implies that $\mathbb{E}[\int_0^t f(\tau, \omega) dB_\tau] = 0$.

2. *Itô Isometry*.

$$\begin{aligned} & \mathbb{E} \left[\left(\int_0^T f(t, \omega) dB_t \right)^2 \right] \\ &= \mathbb{E} \left[\int_0^T f(t, \omega)^2 dB_t \right]. \end{aligned}$$

An Itô process is a stochastic process which has a representation of the following form:

$$\begin{aligned} dX_t &= u(t, \omega) dt + v(t, \omega) dB_t \\ X_t &\in \mathbb{R}^n, u(t, \omega) \in \mathbb{R}^n, v(t, \omega) \in \mathbb{R}^{n \times m}, \end{aligned}$$

where B_t is an m -dimensional Brownian motion. An important result is the Itô's formula, which states that for a given, twice-differentiable function $g(t, x) \in C^2([0, \infty) \times \mathbb{R}^n)$, the process

$Y_t = g(t, X_t)$ is also an Itô process whose k th coordinate has a representation

$$\begin{aligned} dY_k &= \frac{\partial g_k}{\partial t}(t, X) dt + \sum_i \frac{\partial g_k}{\partial x_i}(t, X) dX_i \\ &+ \frac{1}{2} \sum_{i,j} \frac{\partial^2 g_k}{\partial x_i \partial x_j}(t, X) dX_i dX_j, \end{aligned}$$

where $dB_i dB_j = \delta_{ij} dt$, $dB_i dt = dt dB_i = 0$. The Itô's formula generalizes the chain rule of elementary calculus as can be seen by substituting $v = 0$ in the above equation. Another important concept is the notion of an *infinitesimal generator* of an Itô diffusion. If X_t is a time-homogeneous Itô diffusion, then the infinitesimal generator A of the process X_t is defined as

$$Af(x) = \lim_{t \rightarrow 0} \frac{\mathbb{E}^x[f(X_t)] - f(x)}{t},$$

where $f : \mathbb{R}^n \rightarrow \mathbb{R}$. Here, we have used the notation $\mathbb{E}^x[f(X_t)] = \mathbb{E}[f(X_t) | X_0 = x]$. After applying Itô's formula to $f(X_t)$, where X_t satisfies the homogeneous equation

$$\begin{aligned} dX_t &= b(X_t) dt + \sigma(X_t) dB_t \\ X_t &\in \mathbb{R}^n, b(x) \in \mathbb{R}^n, \sigma(x) \in \mathbb{R}^{n \times m} \end{aligned}$$

with $X_0 = x$ we arrive at the following:

$$\begin{aligned} f(X_t) - f(x) &= \int_0^t \left(\sum_{i=1}^n b_i(X_s) \frac{\partial f}{\partial x_i} \right. \\ &+ \frac{1}{2} \sum_{i,j} [\sigma \sigma^T]_{ij}(X_s) \frac{\partial^2 f}{\partial x_i \partial x_j} \Big) ds \\ &+ \sum_{i,k} \int_0^t \sigma_{ik} \frac{\partial f}{\partial x_i} dB_k \end{aligned}$$

On taking expectations and letting $t \rightarrow 0$, we arrive at the action of the infinitesimal generator of the diffusion as

$$Af(x) := \langle \nabla f(x), b(x) \rangle + \frac{1}{2} \text{tr}(\sigma(x) \sigma^T(x) \nabla^2 f(x)),$$

where ∇ denotes the gradient operator and ∇^2 is the Hessian matrix. Infinitesimal generators arise naturally in the optimal control problem and serve as an important link

between problems in stochastic control and partial differential equations.

FORMULATION OF THE OPTIMAL CONTROL PROBLEM

In this section, we provide a classification of the optimal control problems based on the information available to the controller. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space equipped with the filtration $\{\mathcal{F}_t\}$ and an m -dimensional $\{\mathcal{F}_t\}$ -Brownian motion $\{B_t\}$. $\mathcal{F}_t$ denotes the total information available to the controller at time $t \geq 0$. The state evolution is given by the following SDE:

$$\begin{aligned} dX_t &= dX_t^u = b(t, X_t, u_t) dt + \sigma(t, X_t, u_t) dB_t, \\ X_s &= x \in \mathbb{R}^n. \end{aligned}$$

The notation X_t^u refers to the state trajectory obtained when the control action is u_t . The control action u_t is restricted to the Borel set $U \subset \mathbb{R}^k$. Given the state evolution equation, an optimal control problem is characterized by specifying the class of *admissible control* $\mathcal{A}$ and the *cost function* $J(s, x, u)$. The different classes of admissible controls which are typically considered, are as follows:

Open-Loop Control. In this class, the control actions are functions of the form $u(t, \omega) = u(t)$. This specifies a deterministic control action which does not depend on any observation except maybe the initial condition $X_0 = x$.

Feedback Control. This class consists of control functions which are adapted to $\{\mathcal{F}_t^X\}$, where $\mathcal{F}_t^X$ is the σ -algebra generated by $\{X_r; s \leq r \leq t\}$; that is at each time t , the control $u(t)$ is a function of the observed trajectory $X([s, t])$. In the context of game theory, such control strategies are also known as *behavioral strategies*.

Markov Control. This is a subclass of feedback control actions with the additional property that the control action is of the form $u(t, X(t))$; that is the control action is only dependent on the current state. If further, we have that the control action is of the form $u(X(t))$ then

it is known as the *stationary Markov control*.

Partial Information. This class of controls refer to the case when the controller has partial information about the system state. In many instances, this partial information Z_t is modeled as an outcome of an SDE of the following form:

$$dZ_t = a(t, X_t) dt + \gamma(t, X_t) d\hat{B}_t.$$

The control action is required to be adapted to the σ -algebra generated by the observation process Z_t .

OPTIMAL CONTROL UNDER FULL STATE INFORMATION

In this section, we discuss various formulations where the controller has access to the state vector. As expected, the analysis of such problems tend to be simpler compared to problems when the controller has access to partial information about the state.

Infinite Horizon Discounted Cost Problem

Here, we provide an informal derivation of the HJB equation for the case of infinite horizon discounted cost problem. We assume that the state equation follows the homogeneous SDE

$$\begin{aligned} dX_t &= dX_t^u = b(X_t, u_t) dt + \sigma(X_t, u_t) dB_t, \\ X_0 &= x \in \mathbb{R}^n. \end{aligned}$$

The cost structure of the infinite horizon discounted time problem is given as

$$J(x, u) = \mathbb{E} \left[\int_0^\infty e^{-\gamma t} c(X_t, u_t) dt \mid X_0 = x \right].$$

Here $c(X_t, u_t)$ denotes the running cost and γ is a discount factor which is included to ensure integrability conditions on the cost and the value function. In certain economic applications, γ also has the interpretation of interest rates which is used to discount the cost to get its present value. A high value of

γ tends to make the control action myopic in nature since it discounts the future more heavily. The optimal control problem is to find the control action in the admissible set which minimizes the cost function. The optimal cost achieved is known as the *value function* $V(x)$ which has the following representation:

$$V(x) = \inf_{u \in \mathcal{A}} J(x, u).$$

We define the set of admissible controls $\mathcal{A}$ as the set of Markov controls. The *principle of optimality* can be used to arrive at the following equation which is satisfied by the optimal cost function:

$$V(x) = \inf_u \mathbb{E} \left[\int_0^t e^{-\gamma\tau} c(X_\tau, u(X_\tau)) d\tau + e^{-\gamma t} V(X_t) \right]. \quad (3)$$

Here, we make the simplifying assumption that there exists an optimal control u^* for which the value function is achieved, that is, $V(x) = J(x, u^*)$. The HJB equation is a partial differential equation which is obtained when we let the time approach zero. The derivation of the HJB equation for the discounted cost problem is as follows: By applying Itô's rule to the term $e^{-\gamma t} V(X_t)$, we arrive at

$$\begin{aligned} & \mathbb{E} \left[\int_0^t e^{-\gamma\tau} c(X_\tau, u(X_\tau)) d\tau + e^{-\gamma t} V(X_t) \right] \\ &= V(x) + \mathbb{E} \int_0^t e^{-\gamma\tau} (-\gamma V(X_s) + A^u V(X_\tau) \\ & \quad + c(X_\tau, u(X_\tau))) d\tau, \end{aligned}$$

where A^u is the infinitesimal generator

$$\begin{aligned} A^u V(x) &:= \langle \nabla V(x), b(x, u) \rangle \\ & \quad + \frac{1}{2} \text{tr}(\sigma(x, u) \sigma^T(x, u) \nabla^2 V(x)). \end{aligned}$$

We assume that $V(x)$ is twice differentiable so that the infinitesimal generator is well defined. Now from Equation (3) we arrive at the following equation which holds for all $u \in \mathcal{A}$:

$$\mathbb{E} \int_0^t e^{-\gamma\tau} (-\gamma V(X_s) + A^u V(X_\tau) + c(X_\tau, u(X_\tau))) d\tau \geq 0,$$

where equality holds with the control u^* . Now taking limit as $t \rightarrow 0$ and assuming that the limit and expectation are interchangeable, we get

$$-\gamma V(x) + A^u V(x) + c(x, u(x)) \geq 0,$$

where equality holds for $u = u^*$ or equivalently,

$$\inf_{u \in U} (-\gamma V(x) + A^u V(x) + c(x, u(x))) = 0. \quad (4)$$

This is the HJB partial differential equation for the infinite horizon discounted cost problem. This equation reduces the problem of the determination of an optimal control in the class of Markov policies to the solution of a partial differential equation. An important thing to note is that like the deterministic optimal control problem, the infinite horizon optimal control problem gives rise to optimal stationary Markov policies.

Optimal Control till a Stopping Time

For discussing the optimal control problem till a stopping time, we will assume that the system dynamics evolve as a nonhomogeneous SDE

$$dX_t = dX_t^u = b(t, X_t, u_t) dt + \sigma(t, X_t, u_t) dB_t,$$

with the initial condition $t_0 = s$ and $X_s = x$. Given the algebra generated by X_t as $\mathcal{F}_t^X$, a stopping time τ is an extended real-valued random variable which satisfies $\{\tau \leq t\} \in \mathcal{F}_t^X$ for all t . Let G be a fixed domain in $\mathbb{R} \times \mathbb{R}^n$ and τ_G be the first exit time after s by the process, that is,

$$\tau_G = \inf\{t > s; (t, X_t) \notin G\}.$$

It can be checked that τ_G is a stopping time. The optimal control problem is to minimize the cost function

$$\begin{aligned} J(s, x, u) &= \mathbb{E} \left[\int_s^{\tau_G} c(r, X_r) dr \right. \\ & \quad \left. + h(\tau_G, X_{\tau_G}) \chi_{\{\tau_G < \infty\}} \mid X_s = x \right], \end{aligned}$$

where $h(\tau_G, X_{\tau_G})$ is the terminal cost. It can be easily seen that by choosing $G = [0, T) \times \mathbb{R}^n$, the problem reduces to a finite time horizon problem with horizon T . Clearly, in this case, the value function is dependent on the initial time as well, that is,

$$V(s, x) = \inf_{u \in \mathcal{A}} J(s, x, u).$$

The HJB equation associated with this problem can be written as

$$\frac{\partial V(t, x)}{\partial t} + \inf_{u \in U} [A^u(t)V(t, x) + c(t, x, u)] = 0, \quad (5)$$

with the boundary condition $V(t, x) = h(t, x)$ for all $(t, x) \in \partial G$, where ∂G denotes the boundary of the set G . Various conditions under which the solution of the HJB equation is guaranteed to exist are given in Ref. 2. One of them is a *uniform ellipticity* condition which requires that there exists a k such that the following holds:

$$\sum_{i,j} (\sigma \sigma')_{i,j} \xi_i \xi_j \geq \|\xi\|^2 \quad \forall \xi \in \mathbb{R}^n.$$

This condition essentially means that noise affects every component of the SDE regardless of the coordinate system. We now present a *verification theorem* [2] which gives sufficient condition for optimality.

Theorem 1. *Let $V(s, x)$ be a solution of the HJB equation (Eq. 5) which satisfies the boundary condition mentioned above. If in addition the solution $V(s, x)$ has well-defined partial derivatives $V_s, V_{x_i}, V_{x_i x_j}$; is continuous on the closure $\bar{G}$; and satisfies the polynomial growth condition for some D, k such that $|V(t, x)| \leq D(1 + |x|^k)$ when $(t, x) \in G$, then we have*

1. $V(s, x) \leq J(s, x, u)$ for any admissible control u and initial condition $(s, x) \in G$;
2. if u^* is an admissible feedback control such that

$$\begin{aligned} & A^{u^*}(s)V(s, x) + c(s, x, u^*) \\ &= \min_{u \in U} [A^u(s)V(s, x) + c(s, x, u)] \end{aligned}$$

for all $(s, x) \in G$, then $V(s, x) = J(s, x, u^*)$ for all $(s, x) \in G$. Thus, u^* is optimal.

The following example is an interesting application of the HJB equation to the problem of portfolio selection. This problem was first formulated by Merton and is one of the few problems for which an analytical solution is available.

Example. Optimal Portfolio Selection [3]: Consider an investor whose wealth at time t is denoted by X_t . At each instant, the investor needs to make a decision about the fraction of wealth to invest in a stock which is denoted as $\alpha^1(t)$ and the amount of wealth to consume. The amount of wealth consumed by time t is denoted $\alpha^2(t)$. The unconsumed and uninvested stock can grow at a risk-free interest rate of r . The price of the risky asset (stock) denoted as $S(t)$, changes according to

$$dS = RS dt + \sigma S dW,$$

where r, R , and σ are constants and moreover, $R > r > 0$ with $\sigma \neq 0$. The evolution of the total wealth is given by the SDE

$$\begin{aligned} dX = & (1 - \alpha^1(t))Xr dt + \alpha^1(t)X(R dt + \sigma dW) \\ & - \alpha^2(t) dt. \end{aligned}$$

Define $G := \{(t, x) \mid 0 \leq t \leq T, x \geq 0\}$ and the stopping time τ is the first exit time from G . The control action is denoted by $u(t) = (\alpha^1(t), \alpha^2(t))$. The payoff functional to be maximized is

$$J(x, u) = \mathbb{E} \left[\int_t^\tau e^{-\gamma s} F(\alpha^2(s)) ds \right],$$

where F is a given utility function with $\gamma > 0$ as the discount rate. The HJB equation associated with the problem is given as

$$\begin{aligned} \frac{\partial V}{\partial t} + \max_{0 \leq a_1 \leq 1, a_2 \geq 0} & \times \{ (a_1 x \sigma)^2 / 2 V_{xx} + ((1 - a_1) x r \\ & + a_1 x R - a_2) V_x + e^{-\gamma t} F(a_2) \} = 0 \end{aligned}$$

with the boundary condition $V(0, t) = 0$, $V(x, T) = 0$. The maximum value can be easily computed to be

$$\alpha^{1*} = \frac{-(R-r)V_x}{\sigma^2 x V_{xx}}, \quad F'(\alpha^{2*}) = e^{\gamma t} V_x,$$

given the constraints $0 \leq \alpha^{1*} \leq 1, 0 \leq \alpha^{2*} \leq x$ are valid. Thus, if we know the value function V then we can compute the optimal control policies. It is assumed that the function F is of the form $F(\alpha) = \alpha^\theta$, $0 < \theta < 1$. We proceed by guessing the functional form of the value function as

$$V(x, t) = g(t)x^\theta$$

where $g(t)$ is some function which needs to be determined. The optimal control takes the form

$$\alpha^{1*} = \frac{R-r}{\sigma^2(1-\theta)}, \quad \alpha^{2*} = [e^{\gamma t} g(t)]^{1/(\theta-1)} x.$$

By substituting the value of the optimal control in the HJB equation along with the guessed form of the value function, we arrive at

$$(g'(t) + v\theta g(t) + (1-\theta)g(t)(e^{\gamma t} g(t))^{1/(\theta-1)} x^\theta) = 0, \quad (6)$$

where the constant v is given as

$$v := \frac{(R-r)^2}{2\sigma^2(1-\theta)} + r.$$

Equation (6) is an Ordinary Differential Equation (ODE) which can be solved for $g(t)$ as follows:

$$g(t) = e^{-\gamma t} \left[\frac{1-\theta}{\gamma - v\theta} \left(1 - e^{\frac{-(\gamma - v\theta)(T-t)}{1-\theta}} \right) \right]^{1-\theta}.$$

If $R-r \leq \sigma^2(1-\theta)$, then $0 \leq \alpha^{1*} \leq 1$ and $\alpha^{2*} \geq 0$ as required.

Ergodic Control

Here, we give a brief introduction to ergodic control and we refer the reader to Ref. 4 for a detailed analysis. Ergodic control problems deal with minimization of a time-averaged cost over admissible controls. This cost criterion formulation is useful in scenarios when transients are fast and the effective choice is between different steady states. The cost to be minimized is given as

$$J(x, u) = \limsup_{T \rightarrow \infty} \frac{1}{T} \mathbb{E} \left[\int_0^T c(X_s u_s) ds \right],$$

and the value function is given as

$$V(x) = \inf_{u \in \mathcal{A}} J(x, u).$$

Even though we represent the value functions as a function of the initial state, it turns out that asymptotically the effect of the initial state vanishes and the cost $J(x, u)$ and the value function $V(x)$ are independent of the initial state. The HJB equation associated with the ergodic control problem is obtained by taking limit as $\gamma \rightarrow 0$ in the HJB equation corresponding to the infinite horizon discounted cost problem (Eq. 4). The equation we arrive at is as follows:

$$\inf_{u \in U} (A^u \phi(x) + c(x, u) - \eta) = 0.$$

This equation needs to be solved for both $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ and the constant η . The constant η is the optimal value of the ergodic control problem, that is, $V(x) = \eta$. The function $\phi(x)$ is used to derive the optimal stationary Markov control action as follows:

$$u^*(x) \in \operatorname{argmin}_{u \in U} (A^u \phi(x) + c(x, u)).$$

Risk-Sensitive Control

In this section we provide a brief introduction to the problem of risk-sensitive control as presented in Ref. 5. The risk-sensitive control problem deals with a cost function of the form

$$J(x, u) = \mathbb{E} [\phi(Y)],$$

where $Y = \int_t^T c(s, X_s, u_s) dt + h(X(T))$. The function $\phi(x)$ is an increasing function. A typical choice of the function $\phi(x)$ is of the form $\phi(x) = \rho \exp(\rho x)$. If we assume that $\phi(x)$ is differentiable, then applying Taylor expansion of ϕ around $\mathbb{E}[Y]$, we get

$$\begin{aligned} \phi(Y) &\approx \phi(\mathbb{E}(Y)) + \phi'(\mathbb{E}(Y))(Y - \mathbb{E}(Y)) \\ &\quad + \frac{1}{2}\phi''(\mathbb{E}(Y))(Y - \mathbb{E}(Y))^2. \end{aligned}$$

On taking expectation, we arrive at

$$\begin{aligned} J(s, x, u) &= \mathbb{E}(\phi(Y)) \approx \phi(\mathbb{E}(Y)) \\ &\quad + \frac{1}{2}\phi''(\mathbb{E}(Y))\text{Var}(Y). \end{aligned}$$

Clearly, if $\phi(x)$ is strictly convex around $\mathbb{E}(Y)$ then $\phi''(\mathbb{E}(Y)) > 0$ and the variance term adds to the cost. The optimal control action then tends to minimize the variance and hence, is termed *risk averse*. Similarly when the $\phi(x)$ is strictly concave, the control action is termed *risk seeking*. In the special case when $\phi''(\mathbb{E}(Y)) = 0$, the control is called *risk neutral*. Risk-sensitive control has interesting links to problems in robust control theory. For a detailed analysis of the problem of risk-sensitive control, we refer the reader to Ref. 6.

OPTIMAL CONTROL UNDER PARTIAL INFORMATION

Optimal control problems with partial information arise in a variety of cases when the complete state information is not available to the controller. The partial information is modeled as the outcome of an SDE of the following form:

$$dZ_t = a(t, X_t) dt + \gamma(t, X_t) d\hat{B}_t.$$

The cost function to be minimized is given as

$$\begin{aligned} J(s, x, u) &= \mathbb{E} \left[\int_s^T c(r, X_r, u_r) dr \right. \\ &\quad \left. + h(X_T) \mid X_s = x \right]. \quad (7) \end{aligned}$$

The main idea behind optimal control with partial information is to convert the problem into a problem with full state information by suitably defining a new state vector. In this section, we will restrict ourself to the special case when the state and observation equations are linear. Our presentation in the following section is based on the presentation in Ref. 2. The state and observation equations for the case under consideration is given as

$$dX_t = [A(t)X_t + B(t)u(t)] dt + \sigma(t) dB_t, \quad (8)$$

$$dZ_t = H(t)X_t dt + \gamma(t) d\hat{B}_t. \quad (9)$$

The initial state is a Gaussian random vector X_s and $Z_s = 0$. $\hat{B}_t$ is a standard Brownian motion which is independent of B_t and X_s . At time t , the controller has the information $I_t = \{Z_r : s \leq r \leq t\}$. Such an information pattern is known in the literature as a *classical information pattern*. Let $\mathcal{F}_t$ be an increasing family of σ -algebras such that X_s is $\mathcal{F}_s$ measurable and B_t and $\hat{B}_t$ are $\mathcal{F}_t$ measurable. The control u_t satisfies the following conditions: u_t belongs to the feasible set U and is nonanticipative with respect to $\mathcal{F}_t$. Moreover, it is assumed that $E \int_s^T |u(t)|^k dt < \infty$ for every $k > 0$. Under this assumption, there exists a unique solution of the state equations X_t and the observation equation Z_t . A control is called *nonanticipative* if it assigns the same value for all scenarios with the same past and present. In other words, a nonanticipative control does not anticipate the future evolution. The set of admissible controls satisfying these conditions is denoted by $\mathcal{U}$. Let us define $\mathcal{G}_t^u$ as the σ -algebra generated by the observation process,

$$\mathcal{G}_t^u = \mathcal{F}\{Z_r, s \leq r \leq t\}.$$

Then clearly, we have $\mathcal{G}_t^u \subset \mathcal{U}$. Also, let us define the uncontrolled system as the SDE where $u_t = 0$ as

$$dX_t^0 = A(t)X_t^0 dt + \sigma(t) dB_t,$$

$$dZ_t^0 = H(t)X_t^0 dt + \gamma(t) d\hat{B}_t.$$

We can now apply the Kalman–Bucy filter to arrive at the SDE for the mean square optimal estimate of the the state and the covariance of the error matrix. The mean square

optimal estimate of the state is given by the conditional expectation $\hat{X}_t^0 = \mathbb{E}[X_t^0 | \mathcal{G}_t^0]$, where $\mathcal{G}_t^0 = \mathcal{F}(Z_r^0, r \leq t)$. The Kalman–Bucy filter gives the following SDE for $\hat{X}_t^0$ [2]:

$$\begin{aligned} d\hat{X}_t^0 &= A(t)\hat{X}_t^0 dt + F(t)[dZ_t^0 - H(t)\hat{X}_t^0 dt], \\ \hat{X}_s^0 &= \mathbb{E}[X(s)]; \end{aligned}$$

where $F(t) = R(t)H'(t)[\gamma\gamma'(t)]^{-1}$. The error covariance matrix $R(t) = \mathbb{E}[(X_t^0 - \hat{X}_t^0)(X_t^0 - \hat{X}_t^0)']$ satisfies the matrix differential equation

$$dR = (AR + RA' - RH'(\gamma\gamma')^{-1}HR + \sigma\sigma') dt. \quad (10)$$

We additionally have $Z_t^0 - \int_s^t H(r)\hat{X}_r^0 dr = \int_s^t \gamma(r) dB_r^1$, where B_t^1 is a standard Brownian motion adapted to $\mathcal{G}_t^0$. The term $\int_s^t \gamma(r) dB_r^1$ is known as the *innovation* [7]. Let us also define the deterministic processes X_t^+ and Z_t^+ as the outcome of the ODE:

$$\begin{aligned} dX_t^+ &= [A(t)X_t^+ + B(t)u(t)] dt, \\ dZ_t^+ &= H(t)X_t^+ dt. \end{aligned}$$

Then by linearity of the SDE, we have $X_t = X_t^0 + X_t^+$ and $Z_t = Z_t^0 + Z_t^+$. The following lemma from Ref. 2 characterizes the estimator of the controlled SDE given by Equation (8).

Lemma 1. *If $u(t)$ is $\mathcal{G}_t^0$ measurable and the equality $\mathcal{G}_t^0 = \mathcal{G}_t^u$ holds between the σ -fields of measurements of the uncontrolled and controlled processes, then*

1. *the conditional distribution of X_t given $\mathcal{G}_t^u$ is Gaussian, with mean $\hat{X}_t = \hat{X}_t^0 + X_t^+$ and covariance matrix $R(t)$.*
2. *the conditional mean $\hat{X}_t$ obeys the SDE*

$$\begin{aligned} d\hat{X}_t &= [A(t)\hat{X}_t + B(t)u(t)] dt \\ &\quad + F(t)\gamma(t)dB_t^1, \end{aligned} \quad (11)$$

where B_t^1 is the Brownian motion in the definition of the innovation process.

One of the most important ideas in the control of partially observed systems is the separation principle.

Separation Principle

Before we explain the separation principle, we need to redefine the cost function in terms of the conditional density of the state estimate. Thus, we define

$$p(t, x) = (2\pi)^{\frac{n}{2}} (\det R(t))^{-\frac{1}{2}} \exp \left[-\frac{1}{2} x' R(t)^{-1} x \right].$$

The conditional density of the estimate is given by $p(t, x - \hat{X}_t)$. We define a modified cost function as follows:

$$\begin{aligned} \hat{c}(t, \hat{X}_t, u) &= \int_{\mathbb{R}^n} c(t, x, u) p(t, x - \hat{X}_t) dx, \\ \hat{h}(\hat{X}) &= \int_{\mathbb{R}^n} h(x) p(T, x - \hat{X}), \\ \hat{J}(u) &= \mathbb{E} \left[\int_s^T \hat{c}(t, \hat{X}_t, u(t)) dt + \hat{h}(\hat{X}_T) \right]. \end{aligned} \quad (12)$$

The separation principle states that the optimal control with partial information with classical information pattern can be decoupled into an estimation problem and an optimal control problem with full information. Under a suitable transformation of the state evolution and cost, the problem is converted into a completely observed optimal control problem. The state evolution equation is replaced by the state estimate evolution (Eq. 11). The modified cost is given by Equation (12). The following lemma from Ref. 2 provides a link between the original and modified cost.

Lemma 2. *Under the condition of Lemma 4.1, $J(u) = \hat{J}(u)$.*

Let us define two relevant classes of controls as

$$\begin{aligned} \mathcal{Y}_0 &= \{u \in \mathcal{U} : u(t) \text{ is } \mathcal{G}_t^0 \text{ measurable}\}, \\ \mathcal{Y} &= \{u \in \mathcal{Y}_0 : \mathcal{G}_t^0 = \mathcal{G}_t^u \text{ for } s \leq t \leq T\}. \end{aligned}$$

Then clearly, if we minimize $\hat{J}(u)$ on $\mathcal{Y}_0$ and the minimum $u^* \in \mathcal{Y}$, then by Lemma 4.2 u^* also minimizes $J(u)$ on $\mathcal{Y}$. Wonham in Ref. 8 gives a characterization of control laws

which satisfy the condition $\mathcal{G}_t^0 = \mathcal{G}_t^u$. Let us define $\mathcal{C}^k = \mathcal{C}^k[s, T]$ as the space of continuous functions from $[s, T]$ to $\mathbb{R}^k$ endowed by the sup norm $\|\cdot\|$. Let Γ denote the space of functions γ from $[s, T] \times \mathcal{C}^k$ into the control set U which satisfy the following conditions:

1. If $g(r) = h(r)$ for $s \leq r \leq t$, then $\gamma(t, g) = \gamma(t, h)$.
2. For each $\gamma \in \Gamma$, there exists a constant K such that $\|\gamma(t, g) - \gamma(t, h)\| \leq K\|g - h\|$ for all $g, h \in \mathcal{C}^k$ and $s \leq t \leq T$.
3. $\gamma(\cdot, \cdot)$ is Borel measurable.
4. $\gamma(t, 0)$ is bounded.

Define further a class of controls $\mathcal{Y}_1$ as $\mathcal{Y}_1 := \{u : u(t) = \gamma(t, \eta)\}$. It was shown by Wonham [8] that $\mathcal{Y}_1 \subset \mathcal{Y}$. Thus, if we find an optimal control for $\hat{J}(u)$ in the class $\mathcal{Y}_1$ then the control is also optimal for the cost function $J(u)$ in the class $\mathcal{Y}_0$. We now turn our attention to the linear regulator problem where $U = \mathbb{R}^n$ and the cost function is given by

$$J(x, s, u) = \mathbb{E} \left[\int_s^T (X(t)' M(t) X(t) + u(t)' N(t) u(t)) dt + X(T)' D X(T) \mid X(s) = x \right]. \quad (13)$$

The state estimate evolution is the same as the one mentioned earlier in Equation (11). The modified cost is given by

$$\begin{aligned} \hat{J}(u) &= \mathbb{E} \left[\int_s^T (\hat{X}(t)' M(t) \hat{X}(t) + u(t)' N(t) u(t)) dt + \hat{X}(T)' D \hat{X}(T) \right] + Z, \\ Z &= \mathbb{E} \left[\int_s^T ((X(t) - \hat{X}(t))' M(t) (X(t) - \hat{X}(t))) dt + ((X(T) - \hat{X}(T))' D (X(T) - \hat{X}(T))) \right]. \end{aligned}$$

It can be checked that the term Z is unaffected by control and hence, the term

getting affected by control is the same as in the full information case $J(s, x, u)$ with the state replaced by the state estimate. Thus, the optimal control under partial information has the same functional form as the optimal control under full information with the state vector replaced by the state estimate $u^* = -N^{-1}(t)B(t)'K(t)\hat{X}^*(t)$. The gain $K(t)$ is given by the following matrix Riccati equation:

$$\begin{aligned} \dot{K}(s) &= -K(s)A(s) - A'(s)K(s) \\ &\quad + K(s)B(s)N^{-1}(s)B(s)'K(s) - M(s), \\ K(T) &= D \end{aligned}$$

and the state estimate satisfies the SDE

$$\begin{aligned} d\hat{X}^*(t) &= [A(t)\hat{X}^*(t) + B(t)u^*(t)] dt \\ &\quad + F(t)[dZ^*(t) - H(t)\hat{X}^*(t)dt], \quad (14) \end{aligned}$$

with the initial data $\hat{X}^*(s) = \mathbb{E}[\hat{X}^*(s)]$, where $X^*(t)$ and $Z^*(t)$ are given by the solution of Equations of (2) and (3) respectively, when the optimal control is applied; that is, $u(t) = u^*(t)$.

CONCLUSION AND FURTHER READING

In this article we presented an overview of the basic formulations used in stochastic optimal control. The HJB equation, which is the central equation characterizing optimal control under different cases, was presented. One of the main research problems outside the scope of the current article is characterizing conditions for the existence of a solution to the HJB equation. Some of these conditions are presented in Refs 1, 2, and 6. In Ref. 6, the concept of viscosity solutions to the HJB equation is discussed. It can be shown that for even simple problems, the HJB equation may fail to have a value function which is differentiable. Thus, we need to expand the notion of what a solution to the HJB equation means. A viscosity solution is a generalization of the solution concept for the HJB equation. In this article, we focused on the case where the state evolution is continuous; however, optimal control problems have been formulated in cases when the state evolution is given by a jump diffusion process [9].

STOCHASTIC ORDERS FOR STOCHASTIC PROCESSES

ALFRED MÜLLER
Universität Siegen, Department
Mathematik, Siegen, Germany

MOSHE SHAKED*
University of Arizona, Department of
Mathematics, Tucson, Arizona

Stochastic orders are useful tools for comparing random variables or random vectors, as well as for stochastic processes. Stochastic orders have been applied in all areas where probability is utilized, such as reliability theory, queueing theory, and insurance. Extensive coverage of stochastic orders can be found, for instance, in the monographs by Müller and Stoyan [1] and Shaked and Shanthikumar [2].

We first recall a couple of common stochastic orders for random variables and random vectors. In this article, “increasing” and “decreasing” are used in the weak sense. Expectations are assumed to exist whenever they are mentioned. The real line is denoted by $\mathbb{R}$.

Let X and Y be two random variables with the distribution functions F and G . A stochastic order relation is usually a partial order relation among the corresponding distribution functions. However, with some abuse of terminology, we often say that a stochastic order “compares” random variables, rather than their distribution functions. One of the most common stochastic orders is the so-called the ordinary (or the first order) stochastic order, according to which X is smaller than Y if

$$E\phi(X) \leq E\phi(Y) \quad \text{for all real increasing functions } \phi. \quad (1)$$

We denote this by $X \leq_{\text{st}} Y$, but, as noted earlier, formally this definition really compares

the underlying distribution functions F and G . Another common stochastic order is the so-called the increasing convex stochastic order, according to which X is smaller than Y if

$$E\phi(X) \leq E\phi(Y) \quad \text{for all real increasing convex functions } \phi. \quad (2)$$

We denote this by $X \leq_{\text{icx}} Y$.

Let now $\mathbf{X} = (X_1, X_2, \dots, X_n)$ and $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)$ be two random vectors. The stochastic orders $\leq_{\text{st}}$ and $\leq_{\text{icx}}$ defined in Equations 1 and 2 can be extended to $\mathbf{X}$ and $\mathbf{Y}$ as follows: We say that $\mathbf{X}$ is smaller than $\mathbf{Y}$ with respect to the ordinary stochastic order $\leq_{\text{st}}$ if

$$E\phi(\mathbf{X}) \leq E\phi(\mathbf{Y}) \quad \text{for all real } n\text{-dimensional increasing functions } \phi. \quad (3)$$

We say that $\mathbf{X}$ is smaller than $\mathbf{Y}$ with respect to the increasing convex order $\leq_{\text{icx}}$ if

$$E\phi(\mathbf{X}) \leq E\phi(\mathbf{Y}) \quad \text{for all real } n\text{-dimensional increasing convex functions } \phi. \quad (4)$$

MONOTONICITY AND COMPARABILITY OF STOCHASTIC PROCESSES

We now proceed to stochastic comparisons of stochastic processes. A good reference for this is Chapter 5 in Müller and Stoyan [1], which is based, in turn, on Chapter 4 in Stoyan [3].

Let $\mathbf{X} = (X_t : t \in T)$ be a stochastic process. In this article, the parameter set T (the “time”) can be any subset of the real line, but usually it will be $T = \{0, 1, 2, \dots\}$ or $T = (0, \infty)$. Let $\mathbf{Y} = (Y_t : t \in T)$ be another stochastic process with the same parameter set T as $\mathbf{X}$. We can “think” about $\mathbf{X}$ and $\mathbf{Y}$ as “infinite” random vectors with values in $\mathbb{R}^T$, and then extend Equations 3 or 4 to these infinite vectors. This is usually called *complete comparability*. We now define

*Supported by NSA grant H98230-12-1-0222.

a seemingly weaker notion called *strong comparability*. We say that $\mathbf{X} = (X_t : t \in T)$ is *strongly smaller* than $\mathbf{Y} = (Y_t : t \in T)$ with respect to the order $\leq_{\text{st}}$ (denoted as $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$) if

$$(X_{t_1}, X_{t_2}, \dots, X_{t_n}) \leq_{\text{st}} (Y_{t_1}, Y_{t_2}, \dots, Y_{t_n})$$

for all choices of $\{t_1, t_2, \dots, t_n\} \subseteq T$. (5)

In the case of $\leq_{\text{st}}$, complete comparability and strong comparability are equivalent—see the comment after Theorem 1 in the following. Replacing Equation 5 by

$$X_t \leq_{\text{st}} Y_t \quad \text{for all } t \in T,$$

however, yields an order on $\mathbf{X}$ and $\mathbf{Y}$ that is weaker than $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$.

For a single stochastic process, we can also consider the question of internal monotonicity. We say that a process $\mathbf{X} = (X_t : t \in T)$ is monotone with respect to $\leq_{\text{st}}$, if $X_s \leq_{\text{st}} X_t$ for all $s < t$, and similarly for other orders.

An often successful procedure of establishing $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$ for two stochastic processes is by a construction of a proper coupling; see Lindvall [4] or Thorisson [5]. In the context of stochastic comparisons of stochastic processes, coupling means the joint construction, on the same probability space, of two processes that are conveniently related almost surely. Using couplings, it often may be simple to obtain the desired conclusion of stochastic ordering. For the order $\leq_{\text{st}}$, in the case where the state space of $\mathbf{X}$ and $\mathbf{Y}$ is the real line, the following version of the celebrated Strassen's theorem ensures the desired conclusion (below, “ $=_{\text{st}}$ ” denotes equality in law).

Theorem 1. *The two stochastic processes $\mathbf{X}$ and $\mathbf{Y}$ satisfy $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$ if, and only if, there exists a coupling of two stochastic processes $\hat{\mathbf{X}}$ and $\hat{\mathbf{Y}}$ that satisfy*

$$\begin{aligned} \hat{\mathbf{X}} &=_{\text{st}} \mathbf{X}, \\ \hat{\mathbf{Y}} &=_{\text{st}} \mathbf{Y}, \end{aligned}$$

and

$$\hat{\mathbf{X}} \leq \hat{\mathbf{Y}} \text{ almost surely.}$$

In some situations, the coupling is easy to find, whereas in other cases, it may be quite tricky.

It follows from the earlier-given Strassen's theorem that strong comparability and complete comparability are equivalent for $\leq_{\text{st}}$ ordering. This also implies that the order $\leq_{\text{st}}$ is closed under increasing transformations. This is formally stated next.

Theorem 2. *If the two stochastic processes $\mathbf{X}$ and $\mathbf{Y}$ satisfy $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$ then*

$$\phi(\mathbf{X}) \leq_{\text{st}} \phi(\mathbf{Y})$$

for any (univariate or multivariate) increasing functional ϕ .

A useful consequence of Theorem 2 involves first passage times of the compared processes $\mathbf{X}$ and $\mathbf{Y}$. That is, for some real a consider

$$T_{\mathbf{X}} = \inf\{t : X_t < a\}$$

and

$$T_{\mathbf{Y}} = \inf\{t : Y_t < a\}.$$

Note that $T_{\mathbf{X}}$ and $T_{\mathbf{Y}}$ are increasing functionals of $\mathbf{X}$ and $\mathbf{Y}$, respectively. Thus, we have the following result.

Theorem 3. *If the two stochastic processes $\mathbf{X}$ and $\mathbf{Y}$ satisfy $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$, then*

$$T_{\mathbf{X}} \leq_{\text{st}} T_{\mathbf{Y}}.$$

For discrete-time processes $\mathbf{X} = (X_n : n \in T)$ and $\mathbf{Y} = (Y_n : n \in T)$, with $T = \{0, 1, 2, \dots\}$, we have the following sufficient conditions for the stochastic comparability of $\mathbf{X}$ and $\mathbf{Y}$.

Theorem 4. *Let $\mathbf{X}$ and $\mathbf{Y}$ be two discrete-time stochastic processes. If*

$$X_0 \leq_{\text{st}} Y_0,$$

and if

$$\begin{aligned} & [X_n | X_1 = x_1, \dots, X_{n-1} = x_{n-1}] \\ & \leq_{\text{st}} [Y_n | Y_1 = y_1, \dots, Y_{n-1} = y_{n-1}] \\ & \text{whenever } x_i \leq y_i, \quad i = 1, 2, \dots, n-1, \\ & n = 1, 2, 3, \dots, \end{aligned}$$

then $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$.

This result is a special case of a result from Kamae *et al.* [6].

Complete and strong comparability can also be defined for other stochastic orders, such as the icx order. We say that $\mathbf{X} = (X_t : t \in T)$ is strongly smaller than $\mathbf{Y} = (Y_t : t \in T)$ with respect to the order $\leq_{\text{icx}}$ (denoted as $\mathbf{X} \leq_{\text{icx}} \mathbf{Y}$) if

$$\begin{aligned} & (X_{t_1}, X_{t_2}, \dots, X_{t_n}) \leq_{\text{icx}} (Y_{t_1}, Y_{t_2}, \dots, Y_{t_n}) \\ & \text{for all choices of } \{t_1, t_2, \dots, t_n\} \subseteq T. \end{aligned}$$

A result that is similar to Theorem 2, holds for the order $\leq_{\text{icx}}$, but because of the required convexity that is involved, some continuity restrictions have to be made; see Theorem 5.1.5 in Müller and Stoyan [1]. However, it is shown in Müller and Stoyan (Example 5.1.7 in Ref [1]) that for the order $\leq_{\text{icx}}$, in general, strong comparability and complete comparability are not equivalent.

Regarding internal monotonicity for the order $\leq_{\text{icx}}$, we say that a process $\mathbf{X} = (X_t : t \in T)$ is monotone with respect to $\leq_{\text{icx}}$, if $X_s \leq_{\text{icx}} X_t$ for all $s < t$. It follows easily from Jensen's inequality that any martingale is monotone with respect to $\leq_{\text{icx}}$.

MONOTONICITY AND COMPARABILITY OF MARKOV PROCESSES

First, let us consider a discrete-time homogeneous Markov chain $\mathbf{X}$. That is, $\mathbf{X} = (X_n : n \in T)$ with $T = \{0, 1, 2, \dots\}$. Denote the transition kernel that is associated with $\mathbf{X}$ by $Q_{\mathbf{X}}$, that is, $Q_{\mathbf{X}} = \{q_{i,j}\}$, where

$$\begin{aligned} & q_{i,j} = P\{X_{n+1} = j | X_n = i\}, \\ & i \text{ and } j \text{ vary over the state space of } \mathbf{X}. \end{aligned}$$

The i th row of $Q_{\mathbf{X}}$ is a discrete probability vector $\mathbf{q}_i = (q_{i,j}, j \in \text{state space of } \mathbf{X})$. If the distribution that corresponds to $\mathbf{q}_i$ is stochastically increasing in i (this can be denoted as $\mathbf{q}_i \leq_{\text{st}} \mathbf{q}_j$, whenever $i < j$) then $Q_{\mathbf{X}}$ is said to be stochastically increasing. When $Q_{\mathbf{X}}$ is stochastically increasing, we have the following monotonicity property of the corresponding Markov chain.

Theorem 5. Consider a homogeneous Markov chain $\mathbf{X}$ with transition kernel $Q_{\mathbf{X}}$. If

$$X_0 \leq_{\text{st}} X_1 \quad (6)$$

and if $Q_{\mathbf{X}}$ is stochastically increasing, then $\mathbf{X}$ is stochastically increasing in the sense that

$$X_n \leq_{\text{st}} X_{n+1}, \quad n = 0, 1, 2, \dots \quad (7)$$

Condition 6 is not very stringent, and it holds in many applications. For instance, if the state space of the process has a minimal state in which the process $\mathbf{X} = \{X_0, X_1, \dots, X_n, \dots\}$ starts at time $n = 0$, then Equation 6 evidently holds. Here is an interesting, useful, and simple example.

Example 6. Let $\mathbf{X}$ be a homogeneous birth and death chain, that is, $\mathbf{X}$ has the state space $\{0, 1, 2, \dots\}$, and its transition probabilities are all equal to 0 except perhaps for

$$\begin{aligned} & q_{0,0}, \quad q_{0,1}, \quad q_{i,i-1}, \quad \text{and} \\ & q_{i,i+1}, \quad i = 1, 2, \dots \end{aligned}$$

It is easy to verify that $Q_{\mathbf{X}}$ is stochastically increasing, if, and only if,

$$q_{i-1,i} \leq q_{i,i+1}, \quad i = 1, 2, \dots$$

If the chain starts at $X_0 = 0$ then, by Theorem 5, X_n is increasing in n with respect to $\leq_{\text{st}}$.

If the inequality in Equation 6 in Theorem 5 is reversed, and if $Q_{\mathbf{X}}$ is assumed to be stochastically decreasing, then it can be

shown that $\mathbf{X}$ is decreasing with respect to $\leq_{\text{st}}$.

If the process $\mathbf{X}$ has a stationary distribution, and Equation 7 holds, then the stationary distribution is an upper bound, in the sense $\leq_{\text{st}}$, on the distribution of any X_n .

An analog of Theorem 5 for a continuous-time Markov process and also for the ordering $\leq_{\text{icx}}$ can be stated and proved [[1], Section 5.2].

Applying Theorem 4 to the case of Markov chains yields the following result.

Theorem 7. *Let $\mathbf{X}$ and $\mathbf{Y}$ be two homogeneous Markov chains. If*

$$X_0 \leq_{\text{st}} Y_0,$$

and if

$$[X_{n+1}|X_n = i] \leq_{\text{st}} [Y_{n+1}|Y_n = j] \\ \text{whenever } i \leq j,$$

then $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$.

For two homogeneous continuous-time Markov processes with state space $\{0, 1, 2, \dots\}$, an analog of Theorem 7 also holds [[1], Section 5.2].

Example 8. Recall that a discrete-time homogeneous Markov chain with state space $\{0, 1, 2, \dots\}$ is called *skip-free positive*, if it does not have positive jumps of magnitude more than one. Now, let $\mathbf{X}$ and $\mathbf{Y}$ be two homogeneous Markov chains, both with the state space $\{0, 1, 2, \dots\}$. Suppose that

$$X_0 \leq_{\text{st}} Y_0,$$

$$[X_{n+1}|X_n = i] \leq_{\text{st}} [Y_{n+1}|Y_n = i] \quad \text{for all } i,$$

and

$$[Y_{n+1}|Y_n = i] \geq i \quad \text{for all } i,$$

and that $\mathbf{X}$ is skip-free positive. Then $\mathbf{X} \leq_{\text{st}} \mathbf{Y}$.

ORDERING ELEMENTS OF MARKOV CHAINS

A function $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ is said to be supermodular if for any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ it satisfies

$$\phi(\mathbf{x}) + \phi(\mathbf{y}) \leq \phi(\mathbf{x} \wedge \mathbf{y}) + \phi(\mathbf{x} \vee \mathbf{y}),$$

where the operators $\wedge$ and $\vee$ denote coordinatewise minimum and maximum, respectively. Let $\mathbf{X}$ and $\mathbf{Y}$ be two n -dimensional random vectors such that $E[\phi(\mathbf{X})] \leq E[\phi(\mathbf{Y})]$ for all supermodular functions $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$, provided the expectations exist. Then $\mathbf{X}$ is said to be smaller than $\mathbf{Y}$ in the supermodular order (denoted by $\mathbf{X} \leq_{\text{sm}} \mathbf{Y}$). The supermodular order is often used to compare the strength of positive dependence among the components of the compared random vectors. Only random vectors with the same marginals can be compared with respect to $\leq_{\text{sm}}$. Hence, we consider below a stationary Markov chain, that is, all the X_n have the same marginal distribution. The next result shows that if the transition kernel of the chain is stochastically increasing, then dependence (in the sense of the supermodular order) is decreasing with the lag.

Theorem 9. *Let $\mathbf{X}$ be a stationary homogeneous Markov chain with a stochastically increasing transition kernel. Then*

$$(X_1, X_2) \geq_{\text{sm}} (X_1, X_3) \geq_{\text{sm}} \dots \geq_{\text{sm}}$$

$$(X_1, X_n) \geq_{\text{sm}} \dots \geq_{\text{sm}} (X_1, X^+)$$

where X^+ is an independent copy of X_1 .

The above result is a special case of a result of Hu and Pan [7]. Further results of this type can be found in Kulik and Wichelhaus [8] and Li and Xu [9].

Another interesting result that compares elements of Markov chains involves the hazard rate order. Recall that a random variable X is said to be smaller than another random variable Y in *hazard rate order* if

$$P\{Y > x\}/P\{X > x\} \quad \text{is increasing in}$$

$$x \in (-\infty, \max(u_X, u_Y)),$$

where u_X and u_Y are the right end points of the supports of X and Y , respectively. We denote this as $X \leq_{\text{hr}} Y$. If X and Y are absolutely continuous with density functions f_X and f_Y , distribution functions F_X and F_Y , and

failure rate functions $r_X \equiv f_X/(1 - F_X)$ and $r_Y \equiv f_Y/(1 - F_Y)$, then $X \leq_{\text{hr}} Y$ if, and only if, $u_X \leq u_Y$, and

$$r_X(x) \geq r_Y(x), \quad x \in (-\infty, u_X), \quad (8)$$

Note that if $X \leq_{\text{hr}} Y$ then $X \leq_{\text{st}} Y$. The following result is taken from Ross *et al.* [10].

Theorem 10. *Let $\{X_n^{(i)}, n = 0, 1, \dots\}$ be a homogeneous Markov chain with state space $\{1, 2, \dots, M\}$ (M can be infinity), which starts at state i , that is, $X_0^{(i)} = i$. If*

$$X_1^{(i)} \leq_{\text{hr}} X_1^{(i')} \quad \text{for all } i \leq i'$$

then

- (a) $I_1 \leq_{\text{hr}} I_2$ implies that $X_n^{(I_1)} \leq_{\text{hr}} X_n^{(I_2)}$ for all $n \geq 0$, and
- (b) $X_n^{(1)} \leq_{\text{hr}} X_{n'}^{(1)}$ whenever $n \leq n'$.

COMPARISONS OF POINT PROCESSES

Let $\{K(t) : t \geq 0\}$ and $\{N(t) : t \geq 0\}$ be two point processes. That is, for each $t \geq 0$, $K(t)$ and $N(t)$ are the numbers of jumps that the corresponding processes have experienced over the time interval $(0, t]$. In addition to the possible relationship $\{K(t) : t \geq 0\} \leq_{\text{st}} \{N(t) : t \geq 0\}$ between these processes, according to the definition in Equation 5, we will also consider the following two other stronger relationships. In these comparisons, the “greater” process is the one with “more” or “denser” points. The discussion that follows is based on Shaked and Szekli [11] and Szekli [12].

For any positive integer n , let $B_1, B_2, \dots, B_n$ be bounded Borel sets of $[0, \infty)$. Let $K(B_i)$ and $N(B_i)$ denote the number of jumps of the corresponding processes with jump times in the set B_i , $i = 1, 2, \dots, n$. Suppose that for all choices of an integer n and bounded Borel sets $B_1, B_2, \dots, B_n$, it holds that

$$(K(B_1), K(B_2), \dots, K(B_n)) \leq_{\text{st}} (N(B_1), N(B_2), \dots, N(B_n)),$$

where, also here, the relation $\leq_{\text{st}}$ is in the sense of 3. Then $\mathbf{K} = \{K(t) : t \geq 0\}$ is said to be smaller than $\mathbf{N} = \{N(t) : t \geq 0\}$ in the usual stochastic order over $\mathcal{N}$, where $\mathcal{N}$ denotes the space of integer-valued Radon measures. This is denoted by

$$\mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N}.$$

This “usual” stochastic order over $\mathcal{N}$ gives a “global” comparison of the point processes $\mathbf{K}$ and $\mathbf{N}$. It is easy to see that

$$\mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N} \implies \mathbf{K} \leq_{\text{st}} \mathbf{N}.$$

Next, let $X_1, X_2, \dots$ be the sequence of interpoint distances of the process $\mathbf{K}$, and let $Y_1, Y_2, \dots$ be the sequence of interpoint distances of the process $\mathbf{N}$. We assume that the X_i s and that the Y_i s are almost surely positive. Moreover, we assume that the processes are nonexplosive in the sense that $\lim_{n \rightarrow \infty} \sum_{i=1}^n X_i = \infty$ and $\lim_{n \rightarrow \infty} \sum_{i=1}^n Y_i = \infty$ almost surely. Suppose that, for all choices of an integer n and indices $i_1, i_2, \dots, i_n$, it holds that

$$(X_{i_1}, X_{i_2}, \dots, X_{i_n}) \geq_{\text{st}} (Y_{i_1}, Y_{i_2}, \dots, Y_{i_n}),$$

where, also here, the relation $\leq_{\text{st}}$ is in the sense of 3. Then $\mathbf{K}$ is said to be smaller than $\mathbf{N}$ in the usual stochastic order over $\mathbb{R}^\infty$, and is denoted by

$$\mathbf{K} \leq_{\text{st}-\infty} \mathbf{N}.$$

The usual stochastic order over $\mathbb{R}^\infty$ gives a “local” comparison of the point processes $\mathbf{K}$ and $\mathbf{N}$. Also here it is easy to see that

$$\mathbf{K} \leq_{\text{st}-\infty} \mathbf{N} \implies \mathbf{K} \leq_{\text{st}} \mathbf{N}.$$

It has been shown that, in general,

$$\mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N} \not\Rightarrow \mathbf{K} \leq_{\text{st}-\infty} \mathbf{N}$$

and also that

$$\mathbf{K} \leq_{\text{st}-\infty} \mathbf{N} \not\Rightarrow \mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N}.$$

The most interesting applications of the previous orderings of point processes are

stochastic comparisons of renewal processes. We describe some of these in the following. The proofs of the following results can be found in Shaked and Szekli [11] and Szekli [12].

Theorem 11. *Consider two nondelayed renewal processes $\mathbf{K}$ and $\mathbf{N}$ with generic interpoint distances X and Y , respectively. The following three statements are equivalent.*

- (i) $Y \leq_{\text{st}} X$,
- (ii) $\mathbf{K} \leq_{\text{st}} \mathbf{N}$,
- (iii) $\mathbf{K} \leq_{\text{st}-\infty} \mathbf{N}$.

Theorem 12. *Consider two delayed renewal processes $\mathbf{K}^d = \{K^d(t) : t \geq 0\}$ and $\mathbf{N}^d = \{N^d(t) : t \geq 0\}$, with the corresponding delays X^d and Y^d and with the same interrenewal distribution after the delay. The following statements are equivalent.*

- (i) $Y^d \leq_{\text{st}} X^d$,
- (ii) $\mathbf{K}^d \leq_{\text{st}} \mathbf{N}^d$,
- (iii) $\mathbf{K}^d \leq_{\text{st}-\infty} \mathbf{N}^d$.

The next result gives conditions for $\leq_{\text{st}-\mathcal{N}}$ in terms of the failure rates.

Theorem 13. *Consider two nondelayed renewal processes $\mathbf{K}$ and $\mathbf{N}$ with generic interpoint distances X and Y , respectively. Let r_X and r_Y denote the failure rate functions that correspond to X and Y , respectively. If*

$$r_X(t) \leq r_Y(s) \quad \text{for all } 0 \leq s \leq t \quad (9)$$

then

$$\mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N}.$$

Note that if $Y \leq_{\text{hr}} X$ (in the sense of Eq. 8) and if X is DFR (i.e., has decreasing failure rate) or if Y is DFR, then Equation 9 holds.

Theorem 14. *Consider two delayed renewal processes $\mathbf{K}^d$ and $\mathbf{N}^d$, with the corresponding delays X^d and Y^d and with*

the same interrenewal distribution after the delay. Let r_d denote the failure rate function corresponding to X^d . If $Y^d \leq_{\text{hr}} X^d$ and if

$$r_{X^d}(t) \leq r(s) \quad \text{for all } 0 \leq s \leq t, \quad (10)$$

where r is the failure rate function associated with the common interrenewal distribution function, then

$$\mathbf{K}^d \leq_{\text{st}-\mathcal{N}} \mathbf{N}^d.$$

Denote by X a generic interpoint distance in Theorem 14. We note that Equation 10 holds if $X \leq_{\text{hr}} X^d$, and if X is DFR or if X^d is DFR.

Finally, we give conditions for two nonhomogeneous Poisson processes to be ordered according to the earlier-mentioned orders. Recall that for a nonhomogeneous Poisson process $\mathbf{K} = \{K(t) : t \geq 0\}$, the mean function $M_{\mathbf{K}}$ is defined by $M_{\mathbf{K}}(t) = E[K(t)]$, $t \geq 0$, and the intensity function $\lambda_{\mathbf{K}}$ is defined by $\lambda_{\mathbf{K}}(t) = (d/dt)M_{\mathbf{K}}(t)$, $t \geq 0$.

Theorem 15. *Let $\mathbf{K}$ and $\mathbf{N}$ be two nonhomogeneous Poisson processes with mean functions $M_{\mathbf{K}}$ and $M_{\mathbf{N}}$, respectively, and with intensity functions $\lambda_{\mathbf{K}}$ and $\lambda_{\mathbf{N}}$, respectively.*

- (i) *If $M_{\mathbf{K}}(t) \leq M_{\mathbf{N}}(t)$, $t \geq 0$, then $\mathbf{K} \leq_{\text{st}} \mathbf{N}$.*
- (ii) *If $\lambda_{\mathbf{K}}(t) \leq \lambda_{\mathbf{N}}(t)$, $t \geq 0$, then $\mathbf{K} \leq_{\text{st}-\mathcal{N}} \mathbf{N}$.*
- (iii) *If $M_{\mathbf{K}}^{-1}(M_{\mathbf{N}}(t)) - t$ is increasing in $t \geq 0$, then $\mathbf{K} \leq_{\text{st}-\infty} \mathbf{N}$.*

There is also a vast literature on stochastic comparison of more general stochastic processes, for which we give only some references. An important paper on the comparison of solutions of stochastic differential equations in the sense of $\leq_{\text{st}}$ is Ikeda and Watanabe [13]. For a similar ordering result in the increasing convex ordering sense, Hajek [14] is a good reference. Many interesting comparison results for semimartingales and Lévy processes can be found in Bergenthum and Rüschendorf [15]. Finally, there are also a number of papers on the comparison of generalizations of Poisson

processes, trying to formalize in queuing theory the intuition that more variable arrival processes lead to worse performance of the queuing system; see Miyoshi and Rolski [16] for an overview.

STOCHASTIC SEARCH METHODS FOR GLOBAL OPTIMIZATION

ZELDA B. ZABINSKY
Department of Industrial and
Systems Engineering,
University of Washington,
Seattle, Washington

Stochastic search methods, or random search algorithms, incorporate some form of randomness in the execution of the algorithm. They are frequently applied to ill-structured global optimization problems, in which the objective function and constraints may be black-box functions and only the function value or membership oracle (constraint satisfaction) is available. The decision variables may be continuous and/or discrete. There are many such global optimization problems that arise in engineering applications of complex systems as well as economic and biological systems.

In contrast to deterministic methods, stochastic search methods sacrifice a strong convergence property for a weaker probabilistic result. However, some stochastic methods can provide a relatively good solution with polynomial time complexity, on the average [1], for many problems where deterministic methods are known to be NP-hard. For example, estimating the volume of a convex body using a deterministic method requires an exponential number of function evaluations, but a stochastic search method can estimate the volume with a high probability of being correct in polynomial time [2,3]. In an optimization context, Zabinsky and Smith [4,5] showed that, if one could sample uniformly from improving regions, then the expected number of such iterations to achieve a solution arbitrarily close to the global optimum with high probability

increases at most *linearly* in dimension. This theoretical sampling was called *pure adaptive search* (PAS). A theory on when linear complexity, on average, may be achieved was developed through the analysis of PAS and subsequent constructs of annealing adaptive search (AAS), and hesitant adaptive search (HAS) (see the article titled ***Random Search Algorithms***, or Zabinsky [4] for an overview). These analyses suggest that stochastic search methods can be efficient and effective and have motivated the development of recent algorithms.

In this article, we discuss several algorithms that were motivated by the ideal performance of PAS and subsequent analyses of AAS and HAS, and utilize hit-and-run as a Markov chain Monte Carlo sampler to develop approximating algorithms. There is a companion article in this encyclopedia (see ***Random Search Algorithms***), which describes PAS, AAS, and HAS in more detail and gives an overview of algorithms, but does not give a detailed description of the algorithms, as found in this article. This article emphasizes algorithms utilizing Markov chain Monte Carlo samplers, including improving hit-and-run (IHR) and hide-and-seek, which fall into the category of simulated annealing algorithms. It also summarizes how the analysis of AAS motivated an analytically derived cooling schedule and in the category of multistart methods, the analysis of HAS motivated a stopping and restarting criterion. Hit-and-run has also been used in the context of an interacting particle algorithm. The assumption in this article is that the objective function can be evaluated, even though it may be a black-box function, whereas the article titled ***Random Search Algorithms*** contains a discussion of algorithms that allow “noisy” objective functions that include randomness and may be available only through a discrete-event simulation or experiment.

GENERAL STOCHASTIC SEARCH ALGORITHM

We consider a general global optimization problem (P) defined as,

$$(P) \quad \min_{x \in S} f(x),$$

where x is a vector of n decision variables (continuous and/or discrete), f is a real-valued function defined over S , and S is an n -dimensional feasible region. The objective function f may be a black-box function and no explicit mathematical expression is required. The feasible set S may be represented by a system of equations, such as $g_j(x) \leq 0$ for $j = 1, \dots, m$, or there may simply be a membership oracle that indicates whether x is feasible. Several types of oracles are discussed in Grötschel *et al.* [6], and the membership oracle is the weakest among them, supporting the use of stochastic search algorithms on ill-structured problems. Notice that the feasible region may include both continuous and discrete variables.

We assume that S is nonempty, and that a unique global optimum exists, using the

General Random Search Algorithm

- Step 0.** Initialize algorithm parameters Θ_0 , initial points $X_0 \subset S$ and iteration index $k = 0$.
- Step 1.** Generate a collection of candidate points $V_{k+1} \subset S$ according to a specific *generator* and associated *sampling distribution*.
- Step 2.** Update X_{k+1} based on the candidate points V_{k+1} , previous iterates and algorithmic parameters. Also update algorithm parameters Θ_{k+1} .
- Step 3.** If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

The performance of the algorithm is often characterized by properties of the stochastic processes of points $\{X_k\}$ and objective function values $\{Y_k = f(X_k)\}$. Under certain conditions, they converge in probability to the global optima. Thus, stochastic search methods relax a deterministic convergence result to a probabilistic one.

EXAMPLES OF STOCHASTIC SEARCH ALGORITHMS

The stochastic search algorithms discussed in this article are grouped into categories that are commonly recognized. The first category is simulated annealing algorithms that

notation

$$x_* = \arg \min_{x \in S} f(x) \quad \text{and} \quad y_* = f(x_*) = \min_{x \in S} f(x).$$

If S is compact and f is continuous, or if S is finite and f is finite, the existence of a global optimum is guaranteed. Other regularity conditions on (P) may also ensure the existence of a global minimum. Multiple optima are allowed in many algorithms. We let

$$S(y) = \{x \in S : f(x) \leq y\}$$

denote the level set at y . Typically, the goal of a stochastic search method is to find a point $x \in S(y_* + \epsilon)$ for $\epsilon > 0$.

We describe a general random search algorithm that produces a sequence of iterates $\{X_k\}$ indexed by $k = 0, 1, \dots$ which may depend on previous points and algorithmic parameters. The current iterate X_k may represent a single point, or a collection of points, to include population-based algorithms. The iterates are also capitalized to denote that they are random variables, reflecting the probabilistic nature of the random search algorithm.

broadly include algorithms that maintain and generate a single point at each iteration. The second category is population-based algorithms where a collection of points are maintained and generated at each iteration. The well-known genetic and evolutionary algorithms fall into the second category. The third category is multistart and clustering algorithms that use a sequence of single points in a run, but keep some form of history regarding a collection of points to define a cluster. The fourth category is interacting particle algorithms that combine simulated annealing algorithms with population-based algorithms. The fifth category differs from the others in that it is based on an explicit model

for sampling, and includes cross-entropy as a method.

Simulated Annealing

Simulated annealing algorithms are motivated by the physical process of annealing and were originally proposed for optimization in Kirkpatrick *et al.* [7].

A simulated annealing algorithm has three main components. First a candidate point is generated, in Step 1, according to a transition probability. Then the candidate point is accepted or rejected, in Step 2, according to an acceptance probability. The third component is to update the temperature parameter, which is an important parameter for the acceptance probability. The update procedure for the temperature parameter is referred to as the *cooling schedule*. The most common acceptance probability is the Metropolis criterion [8], where a candidate point V_{k+1} generated from X_k is accepted with probability

$$\min \{1, \exp((f(X_k) - f(V_{k+1})) / T)\}.$$

The sequence of points $\{X_k\}$ can be described as a filtered random walk, governed by the combination of transition probability and acceptance probability distributions. If the temperature parameter T is fixed and the random walk satisfies certain conditions, then its stationary distribution [9,10] is shown to be a Boltzmann distribution with density

$$g_T(x) = \frac{e^{-f(x)/T}}{\int_S e^{-f(z)/T} dz}.$$

Bélisle [11] proved that the sequence of objective function values generated by simulated annealing converges in probability to y_* when the candidate generator has a positive probability of sampling anywhere in the feasible set (as with hit-and-run), and the temperature converges to zero in probability. Ghate and Smith [12] extended this result to generalizations of simulated annealing.

Many candidate point generators have been explored and implemented in simulated annealing algorithms [13,14]. In the continuous domain, the candidate point is often

expressed as

$$V_{k+1} = X_k + S_k \cdot D_k, \quad (1)$$

where X_k is the current point, S_k is a step size, and D_k is a direction vector. In some cases, the direction vector is generated by a stochastic gradient at X_k [15], but there are many algorithms that choose D_k according to a uniform distribution on an n -dimensional hypersphere. The step size S_k is also randomly generated, with limits that may shrink or expand depending on previously sampled points. Typically, the range on step size defines the local neighborhood of the candidate point generator.

The generator called hit-and-run [16] also chooses D_k uniformly on a hypersphere, but the step size is generated uniformly on the set of step lengths that provide a feasible solution along direction D_k , that is, uniformly on $\{s : X_k + sD_k \in S\}$. A feature of hit-and-run is that it is globally reaching, that is, there is a positive probability of sampling anywhere in S from any point X_k . Algorithms that only generate candidate points in a local neighborhood of the current point rely on an acceptance probability to allow the algorithm to accept worse (in terms of objective function value) points and thus escape local minima. Simulated annealing with hit-and-run as the candidate point generator always has a positive probability of sampling within ϵ of the global optimum, no matter what the acceptance probability is, although a carefully chosen acceptance probability can be used to speed up convergence.

The first use of hit-and-run as a candidate point generator had a simple acceptance probability—only accept points with improving objective function values. This is called *IHR*, and it has been successfully applied to realistic problems [17]. The idea of IHR is to approximate the ideal linear performance of PAS, and in Zabinsky *et al.* [18], it was shown that the expected number of function evaluations of IHR to get within ϵ of the optimum is $O(n^{5/2})$ on a certain class of convex programs.

Adding acceptance probabilities according to the Metropolis criterion to the hit-and-run generator was first done in Romeijn and

Smith [19,20], and the algorithm was called *hide-and-seek*. A property of hide-and-seek is that it converges to a Boltzmann T distribution for a fixed temperature [21]. Thus, as the temperature follows a cooling schedule, the algorithm can be viewed as approximating a sequence of Boltzmann distributions parameterized by T . The choice of cooling schedules has been studied extensively. An exponential cooling schedule, $T_k = T_0(\gamma)^k$, is commonly used [7] and Hajek [22] suggested a logarithmic cooling schedule, $T_k = T_0/\ln(k+1)$, that was motivated by an analysis using the maximum “depth” of local minima. For a general cooling schedule, Romeijn and Smith [19,20] showed that if hide-and-seek ran long enough at each temperature value to converge to its stationary Boltzmann distribution, then it would dominate the performance of PAS, and the number of these temperature values would be linear in dimension. This led to an analytically derived adaptive cooling schedule in Romeijn and Smith [20]. The analysis of AAS provided conditions for when a linear complexity on the average number of function evaluations could be achieved. This led to a more comprehensive cooling schedule in Shen *et al.* [23], again motivated by the linear performance, on average, of PAS.

Even though the acceptance probability for simulated annealing is interpreted as aiding the algorithm to escape local optima, simulated annealing has also been successfully applied to convex programs. Bertsimas and Vempala [24] and Kalai and Vempala [25] used hit-and-run as a candidate generator in a simulated annealing-type algorithm for solving convex programs with a membership oracle. In Kalai and Vempala [25], simulated annealing is shown to converge quickly and under certain conditions, the Boltzmann distribution is proven to be optimal for annealing on convex problems.

Using Markov chain methods, Ghate and Smith [26] use dynamic programming to determine the number of iterations of simulated annealing at each decreasing temperature value. Also using results about Markov chains, Nolte and Schrader [27] obtained bounds on the finite-time performance of simulated annealing on various combinatorial problems.

Simulated annealing on finite combinatorial problems uses a candidate point generator that is specifically chosen for that problem. For example, a k -city swap is a candidate point generator for the traveling salesperson problem (TSP) that maintains feasibility of a tour. Another generator for integer variables chooses randomly amongst the nearest neighbors of the current point along coordinate directions. The tabu search [28,29] is a modification of a nearest neighbor generator, where close points are considered “tabu” based on previous evaluations, and only unevaluated points are considered as possible candidates. At the other extreme, very large-scale neighborhood (VLSN) generators are successful for other types of combinatorial problems [30].

When the neighborhood generator is restricted to be local, certain conditions on the acceptance probability and cooling schedule are needed to provide convergence properties. Typically, a slow cooling schedule is required which implies a lot of computation. Jerrum and Sorkin [31] determined that simulated annealing can, with high probability and in polynomial time, find the optimal bisection of a random graph. They used a neighborhood structure specific to their problem. A new version of hit-and-run for discrete [32] or mixed continuous–discrete domains, called *pattern hit-and-run* [33], retains the same property of continuous hit-and-run of sampling globally. Thus, it has the same convergence properties for any fixed temperature and cooling schedule as continuous hit-and-run. Specifically, the cooling schedule in Shen *et al.* [23] is derived for integer as well as continuous domains, but its combination with pattern hit-and-run remains for future research.

The proposal distributions of simulated annealing algorithms, as approximations of Boltzmann distributions that concentrate on the global optima, have the potential to provide efficient algorithms as theoretically shown by PAS, AAS, and other analyses. The difficulty is in finding the neighborhood generator and cooling schedule that preserve the desired convergence properties for specific problems. The use of hit-and-run and more recently, pattern hit-and-run are Markov chain Monte Carlo samplers that serve for a

general global optimization problem. More research is needed to incorporate constraints efficiently.

Population-Based Algorithms

Genetic and evolutionary algorithms are population-based random search methods that have been successfully applied toward global optimization. There has been much written on the topic [34,35], and there are several annual conferences and journals dedicated to their study and application. These algorithms are motivated by biological processes, where the concept is to produce “off-spring” of the current population using parameters related to reproduction. Then a selection criterion is applied to create the next generation.

In the context of the general random search where X_k consists of a population of feasible points, Step 1 uses the current population to generate the population V_{k+1} of candidate points, or off-spring. The mechanism used to generate these candidate points consists of cross-over (or recombination) and mutation. The original genetic algorithm of Holland [36] was designed for binary variables and the cross-over mechanism combined two “parents” in X_k and generated two “children” in V_{k+1} by swapping the trailing values in an analogy to the physical cross-over of DNA. The mutation mechanism randomly chooses a binary variable and flips its value. The recombination and mutation mechanisms have many variations and have been extended to continuous variables. Whenever possible, the recombination and mutation mechanisms are tailored to a specific problem to achieve feasibility in a manner similar to how the k -city swap maintains feasibility for the TSP. The mutation element is critical to ensure that the entire feasible region is reachable.

The selection mechanism, as in Step 2, uses the objective function values of the parents and children to mimic “survival of the fittest.” Typically, each candidate point is assigned a selection probability that is used to create the future generation in X_{k+1} . The points with the best objective function values have a higher probability of being selected, which is referred to as *elitism*. However, a

pure elitist strategy converges prematurely and it is recognized that some diversity is needed to converge to a global optimum. An appropriate adaption of the selection probabilities is analogous to a sufficiently slow cooling schedule for simulated annealing. Researchers have used Markov chain analyses to study the behavior of the method [37–39], but tuning of the parameters still requires computational experimentation.

Particle swarm optimization [40,41] is also a population-based stochastic method that is based on the social behavior of birds and schools of fish to locate food. The individuals in the swarm, or population of points in X_k , are typically modeled by position and velocity. The candidate points in V_{k+1} are generated by updating the position based on a scaled step in the direction of the velocity. This resembles the step-size generator of simulated annealing in Equation (1). The updated velocity for each individual is influenced by the overall trend toward the minimum objective function value. In some cases, gradient information is used to update the velocities. In Step 2, the candidate points are all taken for the next population of points, $X_{k+1} = V_{k+1}$, but the updating of velocities can be viewed as a type of selection where better points influence the parameters for the next population. There is also a constraint to maintain a minimum distance between points, so that the swarm does not converge too quickly to a single location.

Ant colony optimization [42] is also a population-based stochastic method based on biology, where the population of ants represent a collection of feasible points. The ants move individually, but communicate through a pheromone that provides feedback on locations with good objective function values. Another population-based stochastic method is differential evolution [43,44] that modifies the genetic cross-over and mutation rules to incorporate a weighted difference between two points to generate a third point. Several of these stochastic algorithms have been numerically tested in Ali *et al.* [45].

A drawback to these algorithms is that the methods of generating new points (e.g., recombination and mutation, or location and velocity) are problem dependent, and require

computational experiments to identify appropriate parameter values. However, the population-based algorithms tend to have efficiencies that single-point algorithms lack, due to the sharing of information during the selection mechanism. Future research is needed to clearly show the impact of various selection mechanisms on efficiency and effectiveness.

Multistart and Clustering Algorithms

Another class of stochastic algorithms is based on the idea of combining a local search with a global search. A natural approach to global optimization, and perhaps the oldest one [46,47], is to apply a local, gradient-type search method with different starting points to determine a local optimum associated with each starting point. Multistart is the term used when a series of different starting points are used to initiate local searches. Typically the starting points are randomly generated, independently and uniformly distributed on S . Although the idea of multistart was originally used with gradient-type searches, multistart has been extended to be used with other local searches as well as globally reaching simulated annealing algorithms.

Multistart is successful in finding many local optima, but there is an inefficiency due to discovering the same local solution from many different starting points. This motivated a class of clustering methods, where clusters of starting points are formed and local searches are only initiated when it is predicted that a new local optimum is likely to be found. Instead of statistically clustering starting points, the well-known multilevel single linkage [48,49] algorithm viewed clusters as trees and “linked” points that led to the same local optima. Several variants include Ali and Storey [50] and Locatelli [51], and a related algorithm called *random linkage* [52,53] was developed. Multistart methods are discussed in Törn and Žilinskas [54] and Laguna and González-Velarde [55], a more recent multistart heuristic in Ugray *et al.* [56], and a successful application to the molecular distance problem in Grosso *et al.* [57].

An important issue in multistart methods is to determine on each single run of an algorithm (local search or perhaps simulated annealing), whether to stop that run and restart with a new run, or whether to terminate completely. Sequential stopping rules for multistart algorithms with pure random search and stratified pure random search were developed in Hart [58] using probability estimates. In Zabinsky *et al.* [59], a stopping and restarting strategy was developed that considered trade-offs between the computational effort and the probability of obtaining the global optimum. The analysis used the theoretical development of HAS, and modeled the behavior of the algorithm to estimate the trade-offs. A framework called dynamic multistart sequential search was developed and numerical tests demonstrate its viability for global optimization.

Multistart and clustering methods provide a means to combine the single-point generation algorithms as in simulated annealing with a collection of points that changes throughout the algorithm.

Interacting Particle Algorithm

The interacting particle algorithm combines the ideas of simulated annealing with population-based algorithms, and is theoretically based on Feynman–Kac systems in statistical physics [60,61]. In Del Moral [60], a general Markov kernel is used as a candidate point generator in Step 1, and a general selection criterion is used in Step 2. A special case of an interacting particle algorithm was developed in Molvalioglu *et al.* [62–64] where hit-and-run was used as the candidate point generator, and a modification of the Metropolis criterion to a population of points (as in Del Moral [60]) was used for the selection mechanism. Specifically, if the candidate points in V_{k+1} are denoted $v_1^{k+1}, v_2^{k+1}, \dots, v_N^{k+1}$, then the point x_i^{k+1} is set to v_j^{k+1} with probability p_j where

$$p_j = \frac{e^{-f(v_j^{k+1})/T}}{\sum_{n=1}^N e^{-f(v_n^{k+1})/T}}.$$

The underlying mathematical model of this interacting particle algorithm is a Boltzmann–Gibbs transformation, which is a special case of the Feynman–Kac measures in Del Moral [60]. As the temperature parameter in the selection criterion goes to zero, the interacting particle algorithm converges to the global optima in terms of the sampling probability distribution. As in simulated annealing with a single particle, the temperature parameter must be chosen carefully to achieve computational benefits.

A numerical study was performed in Molvalioglu *et al.* [62], comparing the interacting particle algorithm to simulated annealing with multistart. Making multiple restarts can also be viewed as having multiple particles instead of a single particle; however, when the restarts are independent, there is no interaction between the particles. The numerical results indicated that there is computational benefit to the interaction.

As in simulated annealing, the temperature parameter T must approach zero for the population to converge. In Molvalioglu *et al.* [63,64], a metacontrol approach was developed to control the temperature parameter in order to speed convergence with a high probability of accuracy. The metacontrol methodology dynamically determines the changes in the temperature parameter by adapting it to the state of the sampling process. The methodology controls the evolution of the probability density function of the particles with the temperature parameter to make the algorithm's search process satisfy user-defined performance criteria. Our performance criteria are directly related to the probability density function of the particles. An interesting feature of the metacontrol approach is that a cooling schedule is not defined *a priori*, but the temperature parameter is adapted to the observed function values. The use of the metacontrol methodology demonstrated that, in contrast to a nonincreasing cooling schedule of temperature in simulated annealing, a dynamic heating and cooling of temperature in the interacting particle algorithm yields enhanced performance Molvalioglu *et al.* [63].

The combination of the interacting particle algorithm with the metacontrol methodology reduces the necessity to have a cooling schedule that works for all problems. The metacontrol methodology can adapt the cooling schedule to the specific problem based on observed function evaluations. More research is needed to adaptively control the parameters of the generation mechanism as well as the selection mechanism.

Cross-Entropy and Other Model-Based Methods

The stochastic search algorithms presented so far generate new candidate points based on the current point or population of points and rely on a set of parameters that govern the transition and acceptance probabilities. Zlochin [65] calls these algorithms *instance-based* methods because they use specific instances of points and function evaluations in determining the next iteration. In contrast, he discusses *model-based* methods that rely on an explicit sampling distribution and update parameters of the probability distribution. These methods are also summarized in another article in this encyclopedia (see **Random Search Algorithms** and **Cross-Entropy Method**) and are just briefly mentioned here.

The most well known of these model-based methods is the cross-entropy method [66,67]. Whereas instance-based methods can be interpreted as a Markov chain sampling method that implies a sampling distribution, the cross-entropy method uses a family of explicit distributions that can be sampled from directly. The idea is based on sequential importance sampling where points are sampled from a sequence of parametrized distributions, and the parameter is updated to minimize the “distance” between the sampling distribution and the target distribution. The target distribution, in the context of global optimization, concentrates its probability on the set of global optima. The distance between the current sampling distribution and the target distribution is estimated by the Kullback–Leibler divergence, also referred to as the *cross-entropy* between two probability distributions. The parameter for the next iteration is chosen to

minimize the Kullback–Leibler divergence between the sampling distribution and the target distribution. Variations of the cross-entropy method have been applied to continuous global optimization problems and combinatorial optimization problems such as the TSP, the quadratic assignment problem, and many other applications. Details of how the update parameters are chosen can be found in Rubinstein and Kroese [66].

Another model-based method is called *model reference adaptive search* (MRAS), and it similarly uses the idea of selecting parameters to bias the sampling distribution toward a degenerate distribution on the global optima. Global convergence properties for MRAS on continuous and discrete domains with noisy objective functions are given in Hu *et al.* [68,69].

Finally, an algorithm aimed at approximating PAS directly, without using a Markov chain Monte Carlo sampler, uses the model of quantum computing for optimization. Baritompä *et al.* [70,71] developed Grover’s adaptive search for optimization using quantum computing. They showed that Grover’s algorithm (originally proposed for database search) could be modified to efficiently generate PAS iterates and thus achieve the ideal linear performance on a quantum computer. Quantum global optimization methods are an exciting area and enlarge the class of stochastic search methods.

SUMMARY

In summary, stochastic search methods have been shown to be effective methods for challenging global optimization problems. The fundamental mechanisms for generating new points are varied and motivated by physical and biological systems, and can be tailored to specific problem formulations. The theoretical treatments for the sampling distributions (as a Markov kernel or a particular form of distribution) provide properties that lead to convergence results. Relating the selection mechanism to a Boltzmann distribution also allows theoretical analyses that can improve algorithm performance. Hit-and-run satisfies

many properties that lead to convergence in probability and approximate desirable complexity results. The model-based methods of cross-entropy and MRAS are also relating sampling methods with target distributions to provide effective algorithms. The idea of metacontrol to incorporate observed function values into modifying parameter values of the generating and selection mechanisms has also shown to improve algorithm performance. Lastly, there is a bright future for quantum global optimization methods.

STRATEGIC AND OPERATIONAL PREPOSITIONING IN CASE OF SEASONAL NATURAL DISASTERS: A PERSPECTIVE

ARUNA APTE
Naval Postgraduate School,
Monterey, CA, USA

INTRODUCTION

The classification of disasters based on time and location and the lifecycle of the disaster are critical for consideration when planning humanitarian assistance [1, 2]. Planners must consider the lifecycle of the disaster that is based on the stages of preparedness, response, and recovery when determining a strategy for disaster relief [3]. Effective logistics in the case of a natural disaster entails getting the necessary emergency supplies and services to the affected population in time. Approximately, 80% of disaster relief involves logistics activities [4]. In the aftermath of a disaster, the distribution and delivery of critical supplies and services to the affected population is a major undertaking. Practitioners [5–7], media, organizational reports, and scholars [3, 8–10] agree that preparation and planning is a significant part of any relief effort.

The objective of all of the organizations involved in humanitarian assistance for these disasters is to reduce human suffering and casualties. Providing relief is largely dependent upon the speed and scope of the response, which is often a function of the level of preparedness that has been established before the disaster event. “Famines occur not because there is not enough food in the world but because the food is not where it is needed” ([11], p. 213). This concept can be applied to disasters, as well: Suffering and casualties often increase owing to disasters because the emergency supplies and services do not reach the affected population in time.

Emergency supplies delivered and services provided depend on not just the provisions and capacities but also the demand estimation [3, 12]. Incorrect demand estimation can force the relief providers to depend on surge, a fairly expensive strategy [2, 13–15]. Forecasting the quantity of demand is a difficult proposition but estimating where and when is even harder [1, 16, 17].

The primary strategies for addressing disasters are prepositioning, proactive and phased deployment, and surge [2, 18–20]. *Prepositioning* is usually understood as the storage of essential commodities to be utilized in disaster relief. However, prepositioning also addresses the issues of capacity planning, facility location for delivering commodities and dispensing emergency services, and strengthening the physical infrastructure. *Proactive deployment* refers to moving supplies into an area in advance of a demand request to reduce lead time. *Phased deployment* normally occurs after the disaster has struck. It refers to pushing inventory into a disaster area as it is needed and in the quantity in which it is needed. A *surge* is the deployment of manpower and supplies from locations outside the disaster area. A surge does not rely on prepositioned inventory but instead relies on established excess capacity. Prepositioned capacity and commodities, a coordinated proactive or phased deployment of assets that leads up to and continues past the time of the disaster, and a surge to supplement these three strategies can eventually attempt to meet the demand spikes and mitigate suffering in all disasters.

The challenges in response supply chains, such as demand surges, the uncertainty of supplies, and the critical time windows in the face of vulnerable infrastructure (both physical and social), raise several serious questions. Finding answers to these questions will result in a more effective and efficient disaster relief. How can demand quantities be estimated [3, 12, 21]? How can

adequate prepositioned disaster relief inventory be established and maintained [22–24]? How reliable are the potential, virtual, and real supply lines [25–32]? Should the supplies be sourced locally (but outside the disaster zone) or should they be imported [33–35]? In addition, the following questions are of special interest for this study: Is prepositioning the best strategy for all types of disasters? Or do there exist certain types of disasters where prepositioning is a better strategy? These are some of the critical decisions faced by humanitarian organizations.

Although all of these questions and strategies are worth researching to facilitate decision-making, in this article, we focus on prepositioning for the following reasons. First, the United Nations [13] and the World Meteorological Organization [15] estimate that every dollar invested in preparing for a disaster saves seven dollars in disaster response. From an economic standpoint, this is a major motivation. In addition, lessons from the military organizations [1, 36] emphasize the importance of prepositioning supplemental resources in or near an incident's location to support operations during extreme conditions. The success of the military in using prepositioned stocks to support operations other than war helps in understanding prepositioning. US Army prepositioned stocks in Southwest Asia and Korea are good examples. One of the significant and often repeated lessons learned from various disasters in the recent past is to be prepared through prepositioning. The analysis of data, based on Action Request Forms issued after Hurricane Katrina made landfall, revealed that regional prepositioning would have expedited the lead time of delivery. In case of a disaster, such prepositioning could be the first wave of relief supplies until more could arrive to the affected area. In addition, such prepositioning could be cost effective if about-to-be-outdated supplies from the safety stock of stockpiles (stored by organizations involved in relief efforts) from nearby locations could be used for such relief [10, 19].

In order to understand prepositioning in humanitarian logistics, we can also derive lessons from commercial supply chains [8].

In the commercial sector, this is similar to prepositioning spare parts and reserve equipment because of the uncertainty of the locations in which parts and equipment will be needed and the uncertainty of the time in which they will be requested. It is also similar to positioning seasonal inventories close to the retail stores during the season and moving them back to warehouses in the off season [37]. In both these cases, forecasting the demand is much easier than in the case of a war or disaster.

We, first, want to clarify what we mean by prepositioning in this article. Prepositioning is divided into two categories: *Strategic* prepositioning occurs long before a disaster strikes, with readiness in mind; and *operational* prepositioning occurs when the disaster is imminent (a response is anticipated within a short lead time) and during the actual response. Strategic prepositioning predominantly involves capacity planning, reinforcing infrastructure, and investigating the needs and availability of various facilities [38–41]. Both the approaches definitely involve the dimension of time in the life cycle of a disaster. However, it needs to be clarified further that the operational prepositioning is also an activity-based approach as it focuses on actually locating the facilities with the appropriate level of inventory, such as warehouses with emergency supplies or triage facilities with medicines [14, 39, 42–48]. Prepositioning, in either approach, is most effective when relatively longer lead times are possible and the frequent location of affected areas such as the “tornado alley” in the southwestern parts of the United States are known or can be estimated.

Natural disasters such as hurricanes, typhoons, and flooding usually occur frequently with certainty during certain seasons in similar locations. For example, hurricanes are most likely to occur in late summer and early fall in the southeastern United States, and typhoons and flooding occur mostly during the monsoon season in Asia. We call these seasonal natural disasters. Although earthquakes occur at a higher frequency in certain locations, they cannot be deemed seasonal because of their

sudden onset, resulting in unpredictability in terms of time.

From the perspective of prepositioning for seasonal natural disasters, only the seasonality offers some insight into planning the disaster relief. In this article, we focus on natural, seasonal disasters, because natural disasters are plentiful, and thus easier to draw inferences from, and because seasonal disasters are relatively more predictable. The prepositioning approach is particularly useful in the case of seasonal natural disasters because of the predictability of both location and timing. In this research, we outline and demonstrate our position on operational and strategic prepositioning. We do this through a literature review in the section titled “Literature Review”, a presentation of our perspective in the section titled “A Perspective”, and a description of caveats in the section titled “The Caveats”. In the section titled “Conclusion”, we offer the conclusions.

LITERATURE REVIEW

Prepositioning, for either approach, has been studied by the scholars [39, 42–50]. Recently, this research has garnered even more interest from academics [51]. See Operations Research to Improve Disaster Supply Chain Management, the humanitarian community, and military organizations—particularly the US military—because of the strategic importance of global humanitarian assistance and disaster relief. More importantly, the operational capabilities of relief providers have improved, perhaps because of the scrutiny and lessons learned from previous disasters and of numerous research and case studies in humanitarian operations. Prepositioning supplies is appropriate when the lead time to respond exceeds the time line for the need. It is also a good solution when critical transportation has to be preserved [34]. Emergency agencies realize the value of designing and reconfiguring disaster relief systems by locating the assets and the facilities based on various objectives. The fact that analytical tools are essential in this effort is well documented in the literature.

Strategic prepositioning, as defined in this article, takes place in the predisaster, preparedness phase in the lifecycle of a disaster [1]. This includes capacity planning of manpower, assets, and resources [3, 50]. Preparedness activities are predominantly strategic and comprise setting the stage for an appropriate response. Operational prepositioning, as defined in this article, mostly takes place before the disaster strikes, is imminent, or even after during the response phase of the lifecycle of a disaster. However, this category is also activity based. For seasonal natural disasters, where the type and location of the disaster can be forecasted results in certain amount of lead time for the relief operations that benefit from both strategic and operational prepositioning.

Facility Location

There are a variety of optimization models available in the literature for facility location in the response phase or operational prepositioning [14, 38–41, 52, 53]. (We would like to note that although all the articles study facility location models, some of the articles also incorporate inventory decisions made way in advance, which does not necessarily conform to our definition of operational prepositioning.) The objective function involves locating the facilities by minimizing the average distance or time and minimizing the maximum distance of the demand points from a facility [14, 40]. Some models involve minimizing the total number of facilities [42, 43], whereas some consist of maximizing reliability [45, 54, 55].

We focus on those models that are developed to locate facilities for disaster relief. Two types of optimization models, the set covering problem (SCP) ([56], pp. 6–7) and the facility location problem (FLP), have been explored by researchers to find solutions to the problem of locating facilities to aid in disaster relief. Surveys of SCPs can be found in Church and ReVelle [57], Brandeau and Chiu [58], and Klose and Drexl [59]. There have been various modifications of the SCP model, as reviewed extensively by Marianov and ReVelle [60], for emergency services. Further studies can be found in the recent

review by Caunhye *et al.* [61] and the references therein.

In the SCP, each facility is associated with a region. This is a binary problem about whether the facility is to be “built/located” or not. In this model, there are no “how to locate” and “transport” decisions to be made, which are typically critical in disaster relief operations (because of the uncertainty surrounding the available manpower, existing infrastructure, and nature of the demand). The FLP is a network-based problem in which one chooses from a candidate list of facilities, making the decision to close or open each individual facility and how much to transport. Certain extensions of these problems also incorporate expansion of the facilities. Both types of models, SCP and FLP, deal with the issue of location, but they address different issues. Traditionally, the FLP is known for facility location in supply chains. However, for emergency services, the SCP or its variants are often used [59].

Approaches developed by researchers are based on the minimum cost covering problem, better known as the location set covering problem (LSCP). The LSCP seeks the minimum number of facilities and their locations so that all demand points are covered. The constraints normally require that all points of demand be covered within a certain time or distance. Satisfying these constraints makes the LSCP a substantial planning tool in disaster relief for locating emergency services because all demand points have to be covered when it comes to an affected population. The models most applicable to emergency service facilities incorporate the maximum time or distance that exists between the user and the service [57, 62–68]. See Introduction to facility location. Such models provide substantial analytical tools for planning for disaster relief.

The maximal covering location problem (MCLP) does not require the coverage of all demand points owing to economic constraints and hence is modeled using a candidate list to pick the best p facilities for maximizing coverage. The MCLP requires finding a subset of p facilities so that maximum (not all) demand can be covered within a given maximal distance. When there is a budget involved, and

there most often is, the MCLP is the natural choice in planning for warehouses and triages in the response phase.

The facility location models have evolved over time, incorporating different constraints based on specific situations of prepositioning discussed in our research. For example, Hale and Moberg [42] specify constraints for locating storage areas for critical emergency equipment and supplies. Whether it is a response to a natural disaster or preparation for famine relief, critical supplies have to be stored in a safe and secure location. Storing these items at every distribution center, manufacturing facility, transportation hub, and office within the supply chain can be unreasonably expensive. Hale and Moberg [42] developed a model with the usual maximum distance constraints found in the generalized SCP. However, they also incorporated constraints for minimum distance between each secured location from each facility. These constraints not only balance operational effectiveness and cost efficiency but also make the solution space smaller and hence more manageable.

Some applications of facility location models with real data can be found in the humanitarian logistics literature. However, such examples that combine rigor and relevance for prepositioning are few. In this article, we offer two succinct examples of establishing facilities for prepositioning in case of disasters.

Balcik and Beamon [39] developed a facility location model to incorporate inventory decisions for a disaster, determining the number and location of distribution centers and the inventory levels at each distribution center. In their study, the authors applied the model to 286 scenarios, each defined by disaster location and its impact; they also considered 45 candidate distribution centers, based on data gathered from the National Geophysical Data Center.

CARE International is one of the largest humanitarian organizations in the world. CARE has adopted disaster preparedness models for providing relief to the affected population of a disaster-struck area by prepositioning items in advance of a disaster

to reduce the response time [14]. Improving agility for acquiring and distributing resources is critical in a disaster situation. Duran *et al.* [14] developed a model evaluating the effects of prepositioning relief supplies on reducing average response time. The findings were applied by CARE when it established its first prepositioning facility in 2008.

Capacity Planning

In addition to the actual storage of commodities or location of emergency facilities, there is also a need to plan for the capacity to deliver essential supplies and services. This type of planning entails the anticipation of a surge in human resources and the availability of an adequate physical infrastructure. This type of prepositioning can be described as capacity planning.

Using a two-stage stochastic optimization model [69] to evaluate disaster response scenarios—through notional scenarios [20] based on public source data—offers viable strategic options. Tean [69] and Heidtke [20] uncovered the important humanitarian logistics questions of “What and how much do they need?” as opposed to “How much can we send?” Salmeron and Apte [50] further investigated this problem of strategic allocation of resources and capacity planning for humanitarian responses to future disasters. We discuss this study in detail in an example later.

Mobile facilities are frequently used to respond to diverse and remote requests for relief. Although transportation has grown to be the second largest operating cost for humanitarian operations since the 1990s [70–72], professional fleet management is almost nonexistent in smaller nongovernmental organizations (NGOs). Research studies have looked at the management of fleets of vehicles for use in capacity planning for a disaster [73, 74], exposing a vein of research for capacity planning in transportation.

A PERSPECTIVE

The literature we have discussed up to this point is divided into two parts because we

believe that it is useful to consider the two types of prepositioning—strategic and operational.

Operational Prepositioning

We have defined operational prepositioning as activity-based prepositioning (such as locating warehouses with stocking of necessary inventory of supplies) that is mostly carried out in the imminent or response phase. For example, this includes the facility location of assets such as warehouses for the storage of consumable supplies, the location of triage facilities for consumable medicines, or the military stocks that can be used for operations other than war. In addition, facility location is necessary for the inventory that is needed for virtually all seasonal natural disasters. The decision of where to preposition supplies must be made with consideration of the trade-offs between reducing the distribution time by placing stocks “near enough” a potentially affected area and placing stocks so close to (or within) a potential disaster area that they are adversely impacted by the disaster when it occurs.

A desirable logistics strategy for disaster events such as the 2004 Indian Ocean tsunami, 2005 Hurricanes Katrina and Rita, and 2010 Pakistan floods could have been locating the supplies outside the potential disaster zone. Prepositioning positively influences the speed of emergency response that is a critical factor in disaster relief [14, 35, 39, 52, 75, 76]. Specifically, Ichoua [76] discussed a model based on scenarios to incorporate locating facilities with inventory and routing decisions, thus encompassing operational and strategic prepositioning, whereas Ukkusuri and Yushimito [75] focus on operational prepositioning by considering disruptions in transportation network. Studies in logistics [50, 77–81] concluded that infrastructure such as distribution centers, warehouses, and medical clinics should be established in locations based on the density of the population and transportation hubs. Location is even more critical when uncertainty is considered [25–32]. Galindo and Batta [82] develop a model specifically taking into account destruction of such locations. An

important, if not *the* most important, stage in the response supply chain is the last mile distribution [22, 83, 84]. In this and many other complex humanitarian logistics systems, the effective and efficient deployment of relief hinges on facility location.

An Example. An example of what can be achieved if academics, practitioners, and emergency planners collaborate in solving the problem of operational prepositioning using analytical tools can be found in the study done by Dekle *et al.* [43]. This study was carried out in the southeastern United States, specifically Florida, where hurricanes from the Gulf of Mexico and the Caribbean often land in late summer and early fall. Federal Emergency Management Agency (FEMA) opens Disaster Recovery Centers (DRCs) in affected areas where such disasters strike. The question is not whether the hurricanes will strike, but where and when they will strike. Dekle *et al.* [43] helped FEMA identify at least three (as required by FEMA) DRC sites in Alachua County, Florida. The decision-making process was designed to be efficient so that it could be implemented based on the parameters of an imminent hurricane during the response phase. The researchers chose from a number of objectives: minimize the average travel distance to the closest DRC, minimize the maximum travel distance to a DRC, minimize the total number of DRCs needed such that all population locations are within a specified distance of the nearest DRC, and maximize the probability that at least one DRC can be useable after the disaster. FEMA and the authors agreed to focus on minimizing the total number of DRCs for three different distances.

The authors formulated the problem as an SCP and solved the original model using aggregate data with Microsoft Excel by solving p -center problems in succession. The emergency management coordinator of the county believed that by having a predetermined list of DRC locations, the agency could provide relief sooner, because of being able to quickly open the facilities and make them operational for upcoming demand of the affected population.

It is important to note that the study's authors accepted the loss of accuracy in reducing the problem size by aggregating the data [85–87]. The 6600 original demand points were reduced to 198 aggregate demand points using Pick-the-Farthest Algorithm. Similarly, 3900 original potential DRC sites were aggregated into 162 sites. They demonstrated that using similar aggregation, the planners can improve solvability and, furthermore, can increase the simplicity of the problem so as to make it more user-friendly. These two attributes of this project made it swiftly executable for operations. It should be noted that this simplification does not capture the entire problem but it is effective. However, the main advantage of this case study was not just the location of DRCs but that the users may not have a single global objective. Other important lessons include the following: The choice of a model may be subjective, data collection is most of the work, and, last but not least, simplification by aggregation of data may be indispensable.

Strategic Prepositioning

Strategic prepositioning involves acquiring services and supplies through capital planning, contracting, or collaboration. It is this prepositioned capacity that leads to response in the time of need. One of the lessons learned after recent seasonal natural disasters, specifically Hurricane Katrina, was that effective and efficient operations cannot be accomplished without strategic prepositioning [10]. Therefore, in addition to storing critical supplies, FEMA has planned evacuation routes and temporary shelters designated in the hurricane-prone region. In other words, FEMA has done some capacity planning.

If a public agency does not have adequate resources to stage prepositioned supplies, it might use networks of volunteers to serve as prepositioned capacity for manpower. FEMA's Response and Recovery Division Director for Region IX noted that the missions such as medical evacuation, planning for commodity distribution, and temporary housing have to be planned before

disaster strikes [6]. Similarly, the US California National Guard recommends that such a disaster response system for prepositioning supplies needs to be in place [7], and the Asia-Pacific Task Force for Emergency Preparedness [88] supports a strategic plan for a more effective emergency preparedness, risk reduction, and disaster response. A discussion of evacuation planning can be found in the studies by Regnier [89, 90] See Evacuation Planning.

An Example. Strategic prepositioning deals with questions such as what level of capacity is needed and can be maintained for warehouses, medical facilities, airfield ramp space, and temporary shelter space? These decisions have to be made substantially ahead of when a disaster strikes. The main objective of strategic prepositioning is to minimize the expected number of casualties. Salmeron and Apte [50] extended the two-stage stochastic optimization model developed by Tean [69] and Heidtke [20] to address vital issues in strategic prepositioning. First-stage decisions involved the expansion of these resources significantly before disaster strikes. In the second stage, these allocated resources were utilized to minimize expected casualties. The study focused on setting up capacity and resources for executing efficient relief operations.

The model handled multiple affected areas that could be affected by disasters for which there may be inadequate probabilistic information. This was possible because of the stochastic element of their model. In order to assess the consequences of prepositioning strategies, the methodology of Salmeron and Apte [50] modeled some of the operational specifics. In the study, the two-stage probabilistic model guided the expansion of capacities: warehouses for critical supplies, medical staff, airstrips, and temporary shelters to minimize expected casualties (their first objective). These second-stage decisions were based on the concept of recourse in which supplies and personnel were deployed after the disaster had occurred and assets had already been allocated. A secondary objective was to minimize the expected

population that would not be transported to the shelters.

The test case used to solve the model and evaluate the results [50], although hypothetical, was based on data using public sources [20, 69] and consultation with the humanitarian community [5, 6]. Computational results on this notional test case provided insights into the problem complexity.

The research study also demonstrated the benefit of using optimization to guide budget allocation. The authors observed that there was a trend in the allocation of the budget to different categories of expansion. They attributed the trend to “(i) the mismatch between the initial MoT capacity and that of health providers, warehouses and ramp spaces, (ii) the budget level, and (iii) planners’ estimates for survival rates and penalties (casualties) for undelivered commodities” [50, p. 573]. The sensitivity analysis performed for different levels of the budget offered interesting insights for emergency planners.

Varying the budget in increments while maintaining expenditure persistence offered insights to the emergency managers. First, as allocation levels increased in warehouses and shelters, the expansion of ramp space and health facilities remained somewhat constant. Results showed that the warehouse capacity was the dominating constraint for minimizing the casualties. Decreasing unsatisfied demand of supplies was explained by the bottleneck shift to warehouse expansion, resulting in the significantly higher expense of rescuing the critical population that was left behind. As the expansion capacity for the shelters diminished, the budget allocation also decreased. One of the significant findings for allocating the budget to different resources was that after a certain level of budget all the allocations evened out with no reduction in the casualties. The research [50] also assessed the benefit of the stochastic model using a perfect information model and averaging scenarios model.

The take-away lessons from Salmeron and Apte [50], for the instance discussed in their article, were as follows: with lower budgets, existing transportation capacity and health capacity for critical populations had to be in line except in the case where the survival rate

was very low or penalties for not meeting the demand were very high. However, as more budgets became available, the expansion of warehouses and meeting the demand became significant because of high cost of special transportation and the exorbitant expense for health facilities for remaining critical population. In general, the research demonstrated that stochastic optimization allows the planner to enter a variety of scenarios by severity or location of the disaster. In addition, their solution accounted for all of the scenarios concurrently without giving any specific importance to some. In addition, logisticians can derive insights from the interaction between increased budgets, their distribution, and the overall effect on the objective.

THE CAVEATS

As demonstrated by the literature in humanitarian logistics and practices in the humanitarian community, prepositioning (strategic and operational) is a strategy that provides significant benefits for effective and efficient humanitarian operations. However, there are some caveats.

One of the caveats about prepositioning is the need to understand the risk associated with the storage of supplies in an area that might be affected by the very disaster for which the relief is aimed [35]. This risk has many facets. Locating the commodities outside the potential disaster area is necessary for timely deployment, but the investment in such inventories could be prohibitively expensive. In addition, the feasibility of maintaining stocks of critical items such as food, water, and medicines for any period of time in countries that are poor, that have high levels of corruption, or that have low governance should be carefully weighed. Any of these situations will affect the security of the prepositioned supplies. Prepositioning medicines adds another wrinkle to the implementation of the strategy. Storing vaccines, antibiotics, and antidotes is appropriate but only when the biological agents created in the aftermath of the disasters to be combated are stable and not mutating.

It is important to note that the success of prepositioning by the military in case of

war cannot be translated to success in prepositioning for humanitarian assistance and disaster relief, as demonstrated in the case of the US Navy described by Apte *et al.* [17]. The assets in the US Navy have capabilities mostly for supporting conflicts and not humanitarian relief. Therefore, deploying them for operations other than war may not accomplish the objective of humanitarian relief. In other words, having prepositioned assets and then deploying them in case of a disaster does not necessarily constitute a good strategy, unless the assets selected are appropriate.

Another difficulty of prepositioning is funding. A significant percentage of donations to humanitarian organizations are earmarked. Such earmarked funding has a negative effect on the prepositioning strategy. Most donors like to see the immediate impact of their contributions following a particular disaster and not sometime in the future. In addition, the earmarked funding cannot be easily used by the organization for any other disaster. To some extent, prepositioning is also a kind of insurance, and there is nothing to “show” if it is not utilized. Although most decision-makers agree on the virtues of prepositioning, the strategy cannot be implemented until the issues around funding are resolved.

Demand estimation constitutes a significant part of prepositioning. The issues to be addressed are quantity, location, and timing of the emergency supplies to be delivered and services to be provided [3, 12]. The mismatch between demand and supply can lead to an inefficient and ineffective disaster relief [2, 13–15]. Demand of the affected population in the future, therefore, can be termed as essential to estimate yet hard to forecast. We, in this article, owing to scope, do not focus on estimation of demand but acknowledge the significant role it plays in prepositioning. Future research in forecasting of demand can play a substantial role.

CONCLUSION

Given the scope and depth of the issues in humanitarian logistics, there are still many unresolved issues—such as the

adequate establishment and maintenance of prepositioned disaster relief inventory; reliability of the potential, virtual, and real supply lines; and decisions about local (but outside the disaster zone) or imported sourcing of supplies—that can be perceived as opportunities to extend the existing literature cited in the first section with further studies. Owing to the scope of this article, there are many details of the prepositioning approach that cannot be addressed here, especially in regard to the inventory to be prepositioned—the type, quantity, and rotation from shelf-life for perishability—as well as the pros and cons of prepositioning. Each one of these topics deserves an article in its own right.

There are strategies other than prepositioning for humanitarian assistance and disaster relief. For reasons discussed at the beginning of this article, we have focused on prepositioning for seasonal natural disasters and have offered our perspective. Further studies could consider how organizations mentioned in this research deal with all types of disasters and not just seasonal natural disasters. Such studies could also enhance the understanding of the prepositioning approaches used for the Strategic National Stockpile, as carried out by the Centers for Disease Control and Prevention.

The scope of the operations, the high uncertainty, and the urgency in the face of inadequate infrastructure are a few of the challenges in humanitarian operations that can be mitigated by sound strategies, specifically prepositioning. Prepositioning can manage the breadth of these challenges through the near-enough location of actual supplies and the availability of capacities for various resources. High uncertainty of demand due to a disaster can be dealt with by prepositioning the majority of relief supplies that are imperishable and commonly necessary in most disasters. Urgency can be eased by reducing the lead time because of the proximity of stockpiles or attention to capacity planning. Strategic prepositioning can improve the inadequate infrastructure.

We outlined and demonstrated our position to shed some light on prepositioning

approaches for relief in case of natural seasonal disaster by addressing two key parts of it: operational and strategic. We described examples to illustrate the development and solution processes that can be used to analyze similar situations. There are many considerations in developing a prepositioning approach, as we explained in the caveats section. These challenges could be explored further.

After studying the literature—research articles and case studies—our findings indicate that, when both the modeling and data employed have been based on input and feedback from experts, the prepositioning models—either operational or strategic—are extremely beneficial for humanitarian relief in the case of seasonal natural disasters. This in turn helps with critical decision-making in humanitarian organizations such as CARE [14] and FEMA [43].

STRATEGIC CUSTOMER BEHAVIOR IN A SINGLE SERVER QUEUE

MOSHE HAVIV

Department of Statistics, The Hebrew
University of Jerusalem,
Jerusalem, Israel

INTRODUCTION

Usually when one considers a queueing model, such as an M/M/1 queue, both arrival and service rates are given. Sometimes an optimization question regarding these parameters is also posed. For example, denote the arrival and service rates by λ and μ , respectively. Suppose the service rate of μ comes with a cost of $c(\mu)$ per unit of time whenever the server is available (and not only while he/she is actually utilized) and it costs C per customer per unit of time in the system. Assume λ to be fixed. Then, one looks for the value of $\mu > \lambda$, which minimizes $c(\mu) + \lambda C/(\mu - \lambda)$, the total social cost per unit of time. In this article we move one step further: it is the individual customers, rather than a central planner, who decide on their actions. Moreover, they do that by optimizing their selfish needs, while ignoring the effect of their moves on others, known as *externalities*. For example, for a given μ , they may decide whether or not to join the queue. It is only their aggregate behavior, which leads to the completion of the model via determining the value of λ . Commencing with the seminal paper [1], this branch of research got much attention in the literature. A state-of-the-art summary (until 2003) on it is given in Ref. 2. We describe below, some of the main results and ideas in this field while considering a few key examples. We limit ourselves to the M/M/1 model with homogeneous (with respect to their cost and rewards parameters) customers. In fact, in this case, strategic behavior is more subtle than in the heterogeneous case.

Customers who consider joining a queue or who are already waiting, may face various types of dilemmas: to join or not to join a queue, to pay or not to pay a fee in order to belong to a high priority class, or whether or not to renege after waiting for a while. We assume that they are selfish and hence maximize their own utility, not minding the externalities that their moves impose on others. While deliberating, they are aware of the fact that other customers may face the same type of dilemma. An individual customer wants to select his/her optimal action, but which action is best depends on what others are doing. For example, if all do not join the queue, it would be better for one to join as this will come with no need to wait, while if all do join, one may face too much waiting and may do best by not joining. Such decision-making problems are best described as noncooperative games. We do not attempt to review, thoroughly, this model. The interested reader is referred to any text in game theory, such as Refs 3 and 4.

In noncooperative games one's utility for any given strategy, is a function of the strategies selected by others. If one's best strategy is not a function of what others do, one's strategy is called a *dominant strategy*. However, in many cases such strategies do not exist and we look for a *pure Nash equilibrium* strategy profile. This refers to a set of strategies, one for each individual, such that each one of them is the best for the corresponding individual, given that all others follow their part in the profile. Yet, the problem may persist: there may not be such a profile.¹ Enlarging the strategy space by allowing mixing (namely, players select a lottery or a probability distribution over their set of pure strategies and assess their utility given their behavior and those of others by the corresponding expected value, when all lotteries

¹As we see below, there is another possible problem: multiple pure equilibria profile may exist.

are carried out independently), may guarantee the existence of a Nash equilibrium. Of course, a pure equilibrium is a special case of a mixed equilibrium.

In all models dealt with below, we assume a symmetric game. This indicates that all customers share the same set of strategies and the same utility function. In particular, customers are homogeneous with respect to their cost/reward parameters. Under a symmetric strategy profile all use the same strategy. Next, for any given such strategy, all assume steady-state conditions under this behavior and all assess their utilities accordingly. Then, we look for a *symmetric Nash equilibrium*, namely an equilibrium profile under which all use the same strategy. More formally, let S be the common set of mixed strategies and let $u(x, y)$ be one's utility if one selects strategy $x \in S$, given that all others select strategy $y \in S$.² Thus, x_e is defined as a symmetric Nash equilibrium if

$$x_e \in \arg \max_{y \in S} u(y, x_e).$$

From now on when we refer to an equilibrium, we mean a symmetric Nash equilibrium.

Let $v(x)$ be the social aggregate utility when all use the strategy x . Typically, $v(x)$ is defined as the sum (or integral) over the individual utilities. A social optimizer looks for an x^* such that

$$x^* \in \arg \max_{x \in S} v(x).$$

Usually, x_e and x^* do not coincide. A mechanism design question is how to manipulate the system so as the resulting new x_e in the manipulated system coincides with the old x^* . This can sometimes be achieved by charging prices on various behaviors. In other cases, more complicated schemes are called for.

Our basic model is that of an M/M/1 queue, namely customers arrive in accordance to a Poisson process with rate Λ and their service times are independent and exponentially

distributed with mean μ^{-1} . Unless stated otherwise, service is granted on a first-come first-served (FCFS) basis. Customers suffer a cost of C per unit of time in the system (inclusive of service) and are rewarded by R due to service completion. In order to avoid trivialities, assume that $R > C/\mu$. Without loss of generality, assume that not joining comes with zero utility.

We are not claiming to supply a comprehensive survey on the field of customers' behavior in queues. Rather, we would like to give the flavor of the issues dealt with, while considering some of the most important queueing decision models. Note that we restrict ourselves to the case where customers are homogeneous with respect to their parameters C and R . Many models where this assumption is removed are also surveyed in Ref. 2. We point out that as opposed to strict optimization problems, the homogeneous case is not a special case of the nonhomogeneous case. In fact, it is usually more difficult for analysis as it calls for the use of mixed strategies under equilibrium, while in the fully heterogeneous case (where no two customers share the same parameter values such as R and/or C), the equilibrium is usually pure under which all use a parameter-dependent pure strategy.

TO QUEUE OR NOT TO QUEUE

The most basic question customers ask is whether or not to join the queue. We next deal with two different scenarios. In the first, customers do not observe the queue while making their decisions and once they join, they cannot change their mind if upon arrival they observe a longer queue than expected. In the second, they observe the queue length upon their arrival and decide whether or not to join based on this information. In both cases we also look at the socially optimal behavior and look for ways to regulate the system by levying appropriate tolls so that the resulting equilibrium behavior coincides with the socially optimal behavior. Finally, we discuss the "avoid the crowd" phenomenon. The results from the unobservable model appear originally in Ref. 5, while

²By utility here and throughout the rest of the article we refer to the expected utility when the two lotteries are carried out independently.

those from the observable case are from Ref. 1. More comprehensive summaries appear, respectively, in Chapters 3 and 2 of Ref. 2.

The Unobservable Case

Equilibrium Behavior. If $\Lambda < \mu$ and all join, then everybody's utility from joining is $C/(\mu - \Lambda) - R$. Thus, if this utility is positive, then joining is a dominant strategy. Indeed, no matter which fraction p of customers join, resulting in a Poisson arrival process with a rate of Λp and with a mean waiting time of $1/(\mu - p\Lambda)$, one's best action is to join. This is not the case where $\Lambda \geq \mu$ or where $\Lambda < \mu$ but $R < C/(\mu - \Lambda)$. Here, a dominant strategy does not exist: if all join, one better not join, and if none of them join, one better join since, as assumed, $R > C/\mu$. The equilibrium strategy is to join with probability p for p obeying $R - C/(\mu - p\Lambda) = 0$. Indeed, under such a p , $0 < p < 1$, if used by all, one is indifferent between joining and not joining, and hence mixing between joining and not joining with probabilities p and $1 - p$, respectively, is a best response for an individual. Such a p is unique. Denoting it by p_e , then

$$p_e = \frac{\mu - \frac{C}{R}}{\Lambda}.$$

Also note that when $p_e < 1$ the utility of all customers, those who join and those who do not, equals zero. No other symmetric equilibrium exists.

To Avoid or to Follow the Crowd. Many decision problems stemming from queueing models possess exactly one of the following two phenomena, that is, when an individual should or should not follow the crowd. Specifically, suppose the set of strategies can be presented by an interval, that is, each strategy corresponds to a number in this interval. This is certainly the case when only two pure strategies are available and the probability with which one option is selected, describes the mixed strategy completely. In particular, the unit interval can be identified with the set of strategies. Let $u(y, x)$ be as defined in the introduction, but now x and y have a numerical value. Define $y^*(x) \in \arg \max_y u(y, x)$. In other words, $y^*(x)$

Figure 1. Avoid the crowd.

is one's *best response* (ties are possible) when all use strategy x . We say that the phenomenon of avoid the crowd (ATC) and follow the crowd (FTC) prevail, when $y^*(x)$ is monotone nonincreasing and nondecreasing, respectively.

The situation we face in the “to queue or not to queue” decision problem is that of ATC. Specifically, suppose all join with probability p . Then $u(q, p)$ is one's utility when one joins with probability q . Note that

$$u(q, p) = \begin{cases} q \left(R - \frac{C}{\mu - p\Lambda} \right), & p\Lambda < \mu \\ -\infty, & p\Lambda \geq \mu. \end{cases}$$

It is easy to see that $q^*(p) = 0$ when $p > p_e$ and $q^*(p) = 1$ when $p < p_e$.³ When $p = p_e < 1$, all strategies are best responses against p_e . As it turns out, symmetric equilibria are the points where the best response function $q^*(p)$ intersects the line $q = p$. By definition, in the ATC case, the best response function is not increasing. The function $q = p$ is of course increasing with p . Hence, the two continuous functions, $q^*(p)$ and p , intersect at exactly one point. In other words, a unique symmetric equilibrium exists in the ATC case (Fig. 1). Things are more involved in the FTC cases as we exemplify later.

³In the case where $p = 1$ is dominant, $p_e = 1$.

Socially Optimal Behavior. In case of a joining probability of p and assuming that $p\Lambda < \mu$, the social gain per unit of time equals

$$p\Lambda \left(R - \frac{C}{\mu - p\Lambda} \right). \quad (1)$$

Thus, a social optimizer looks for the value of p , $0 \leq p \leq 1$, which maximizes Equation (1). Denote this value by p_s . It is easy to see that

$$p_s = \begin{cases} 1, & \Lambda < \mu - \sqrt{\frac{C\mu}{R}} \\ \frac{\mu - \sqrt{\frac{C\mu}{R}}}{\Lambda}, & \text{otherwise.} \end{cases}$$

In the case where $p_s = 1$, the social gain is as stated in Equation (1) with $p = 1$. When $p_s < 1$, it equals

$$(\sqrt{R\mu} - \sqrt{C})^2. \quad (2)$$

It is also possible to see that unless $p_s = 1$, $p_s < p_e$. In other words, left for themselves customers tend to join at a rate, which is higher than is socially desired. This is the case since joining customers ignore the *negative externalities*, in terms of added waiting time to future arrivals, that those who join inflict on each other.

In the case where $p_s < p_e$, by artificially reducing R or increasing C , one can make the new p_e and the old p_s coincide. It is a simple exercise to see that the amount to reduce R with, is $\sqrt{CR/\mu}$, while the amount to increase C with, is $\sqrt{RC\mu} - C$. The former is achieved by imposing an entry fee of $\sqrt{CR/\mu}$ while the latter is achieved by charging customers an extra $\sqrt{RC\mu} - C$ per unit of time in the system, making customers suffer in fact a cost of $\sqrt{RC\mu}$ (instead of C) per unit of waiting time. The collected fees under both charging schemes go to the society's coffer. In both cases individual customers end up with zero utility. Under this optimal entry toll, the social planner collects $(\sqrt{R\mu} - \sqrt{C})^2$ per unit of time. In other words, all consumer surplus as appearing in Equation (2), is transferred completely from the individual customers to the social purse. Such complete transfer of consumer surplus can be achieved when individuals are not more informed than the central planner.

The Observable Case

The model dealt with here is as in the previous section, but with one key distinction: customers observe the queue length upon their arrival and decide whether or not to join accordingly. Thus, a pure strategy in this case means a recipe, which for any possible queue length, prescribes joining or not joining. Assuming that nobody leaves the system after joining it in the first place, and recalling that the service distribution is memoryless, a sensible symmetric strategy will be of the threshold type. By that we mean that there exists some integer value $n \geq 1$, such that all join if and only if the queue length they observe upon arrival is less than n [6].⁴ As a consequence of the FCFS discipline in this observable model, if an individual's utility is not a function of unknown actions taken (or to be taken) by others, a dominant strategy exists.

Equilibrium and Socially Optimal Behavior.

First, the threshold equilibrium behavior is trivial: join if and only if the number in the system is smaller than n_e where⁵

$$n_e = \left\lfloor \frac{R\mu}{C} \right\rfloor. \quad (3)$$

In fact, this strategy is dominant. As opposed to the unobservable case (when Λ is large enough), those who join end up with a positive utility. Second, finding the socially optimal threshold n_s is more cumbersome, but this was done in paper [1].⁶ In particular, n_s is the unique integer value of $n \geq 1$ obeying $g(n-1) \leq \frac{R\mu}{C} \leq g(n)$ where $g(n) = \frac{n(1-\rho) - \rho(1-\rho^n)}{(1-\rho)^2}$. It was shown in Ref. 1 that $n_s \leq n_e$ with equality if and only if $n_e = 1$. By definition, under social optimization the consumer surplus is on average larger than it is under the equilibrium behavior.

⁴Yet, things might be a bit more involved. See Ref. 6 for a formal treatment for this issue.

⁵In the case where $R\mu/C$ is an integer, both n_e and $n_e - 1$ as any mixing between them, define an equilibrium profile.

⁶See Ref. 2, pp. 27–29, for an alternative proof.

As in the unobservable case, individual and social behavior will be aligned by imposing an entry fee or by charging a fee per unit time in the system so that the new n_e coincides with the original n_s . From Equation (3), we learn that any entry fee T obeying

$$n_s = \left\lfloor \frac{(R + T)\mu}{C} \right\rfloor$$

is suitable for this purpose. In other words,

$$\frac{Cn_s}{\mu} - R \leq T < \frac{C(n_s + 1)}{\mu} - R.$$

Under any socially optimal entry fee some of the consumer surplus stays in the hands of the individuals. This is the case since those who join, even after paying the entry fee, end up with a positive utility: The shorter the queue they join, the larger is their surplus. This is the case since customers can adjust their behavior to the actual queue length, while the central planner is limited to a single, one for all price. Put differently, customers are more informed than the social planner is. On the other hand, if a queue length-dependent entry fee is imposed, then all of the consumer surplus can be transferred to the common coffer. Indeed, charging (a bit less than) p_n for one who joins the system when n customers are present, with

$$p_n = \begin{cases} R - \frac{C(n+1)}{\mu} & 0 \leq n \leq n_s - 1 \\ \infty & \text{otherwise.} \end{cases}$$

makes customers behave socially optimal while leaving no surplus in their hands. For more on this pricing see Ref. 7.

Another interesting way to elicit the socially optimal behavior was suggested in Ref. 8. Instead of an FCFS policy, a joining customer is placed at any position but the last one. A possible name for this queueing regime is *not-FCFS*. This allows preempting the one who is in service. In fact, in the case where only one customer is in the system, preempting him/her is the only option. Now all join, but they have the option to renege (i.e., to abandon) as they observe how many

are in front of them. An equilibrium strategy is to renege from the rear of the queue as soon as the total number in the system reaches $n_s + 1$. This leaves the number in the system as it is socially optimal. The reason for this alignment between individual and social behaviors is the fact that the one in the rear of the queue (the one who in fact needs to take decisions) inflicts no externalities on the others under the not-FCFS service policy. Hence, his/her interests and those of the society coincide.

The Case of Processor Sharing or Random Queues

In the case where service is granted so as the next to commence or to conclude service is decided randomly among all those in line was dealt with in Refs 9 and 10. Specifically, a random queue is one where the FCFS discipline is replaced by letting the next to commence service being decided randomly among all those present in line at the epoch of service completion. The processor sharing scheme is such that the server splits in capacity evenly among all those who are present at the system. Yet, in the case of exponential service times, this is equivalent to performing service, but deciding to whom it is granted at random among all those present only in its completion. It is clear that one should better not stay in line if it is too long. In Ref. 10 it is assumed that the one to renege is the last to arrive (who in fact balks upon arrival). Thus, the question here is in fact to queue or not to queue. As expected, an equilibrium policy prescribes joining if and only if the queue length is smaller than some threshold. Yet, since waiting times are also functions of later to arrive customers, true interaction between customers' policies exists here. Specifically, an ATC prevails here and the unique equilibrium policy can be pure or mixed. In the latter case, mixing is among two consecutive threshold queue lengths.

In Ref. 9 it is assumed that as soon as one arrives, he/she is considered as all others. Thus, in case that one needs to leave, all those in line should be treated as equals. It is shown that in this model no equilibrium exists. Yet, an ϵ -equilibrium, for any $\epsilon > 0$

exists.⁷ Under this profile, all stay as long as the total number in queue is smaller than some threshold, renege with some rate when at the threshold (meaning reneging after exponentially distributed time if no change in the number in queue took place in the meanwhile), and when the threshold is crossed, renege at a very high rate (equivalently, in the limit, to performing a lottery, which decides who among those in queue should leave immediately). This is a two-parameter policy (threshold queue length and reneging rate). Ref. 9 shows how to determine it.

TO UPGRADE OR NOT TO UPGRADE

We go on dealing with the previous model but with two key changes. First, customers have the option of belonging to a premium class. Those who belong to this class have preemptive priority over the others, called *regular customers*. Among customers belonging to the same class, FCFS is assumed. Yet, belonging to the premium class comes with a cost of θ . No payment is required for those elected to be regular customers. Second, customers do not have the option of not joining. Thus, from the decision problem point of view of paying or not for priority, the value of service is irrelevant. For stability, we need to assume that $\Lambda < \mu$. To keep our notation standard with the literature, we replace, here, Λ with λ .

The trade-off is between paying for priority and having to wait longer in case of not paying. As all other customers face the same decision problem and as one's waiting time in both classes is a function of the decisions taken by others, the decision model is that of a noncooperative game. In the next section we deal with the unobservable version of the model. Here the strategy space is simple: how to mix between paying and not paying for priority. In the subsequent section we deal with the observable version. There, a pure strategy is more involved, as, for any number of customers from the two groups one may face

upon arrival, one needs to decide if to purchase priority or not.⁸ In the final section titled "How Much To Pay for an Upgrade," we deal again with the unobservable case, but now customers can pay as much as they wish while the more one pays, the higher is one's priority level.

The Unobservable Case

The following appears in Ref. 2. Assume that the symmetric mixed strategy of purchasing priority with probability p is used by all. Then, by standard results from priority queues, the mean time in the system of premium customers is $1/(\mu - \lambda p)$ and that of regular customers is $\mu/[(\mu - \lambda)(\mu - \lambda p)]$. Hence, in this case the added value (which can be negative) from belonging to the premium class in comparison with belonging to the regular class is

$$f(p) \equiv \frac{\rho C}{\mu(1 - \rho)(1 - \lambda p)} - \theta.$$

It is easy to see that $f(p)$ is monotone increasing with p . In other words, the more customers purchase priority, the more priority is valuable to an individual. This is an example of the FTC phenomenon.⁹

The next question is what are the equilibrium values for p . There are three mutually exclusive and exhaustive possibilities:

Case 1: $f(0) \geq 0$. Since $f(p)$ is monotone increasing, it would be better to purchase priority irrespective of how many others do so. In other words, purchasing priority is a dominant strategy. In particular, $p_e = 1$. See Fig. 2a for the best response function.

⁸True, the number of premium customers present in line is irrelevant.

⁹As opposed to "to queue or not to queue" problem where it is *a priori* clear that the ATC phenomenon prevails, the situation here is more subtle. Indeed, the more purchase priority, the less is the number of regular customers to be overtaken by a premium customer (hinting toward ATC). Yet, the more purchase priority, the more one needs priority for oneself in order not to be overtaken by later to arrive premium customers (hinting toward FTC). The latter effect seems to "win" among these two antagonistic forces.

⁷An ϵ -equilibrium, is a strategy profile such that if followed by all, the one who deviates from it can gain at most ϵ .

Figure 2. Follow the crowd.

Case 2: $f(1) \leq 0$. Owing to an argument similar to the one stated in the previous item, not purchasing priority is a dominant strategy. In particular, $p_e = 0$. See Fig. 2b for the best response function.

Case 3: $f(0) < 0 < f(1)$. The first thing to observe is that the two pure strategies define equilibria. Indeed, when all or none purchase priority, it is optimal for an individual to follow suit. But there is a third equilibrium. Let p_e be the unique value such that $f(p_e) = 0$. Of course, such a value exists under the assumption of this case. If all use this strategy, one is indifferent to purchasing priority or not, and hence purchasing priority with probability p_e is one's best response. No other equilibrium exists.¹⁰ The best response function is depicted in Figure 2c. Specifically, when $p < p_e$ the unique best response is 0. It is 1 when $p > p_e$, and any mixing is a best response against all using p_e . Thus, the best response function is nondecreasing. It can hence intersect the 45 degree line more than once. Indeed, this occurs three times: at 0, p_e , and 1. In other words, there are three equilibria as stated in the third item above. Indeed, multiple equilibria are the rule in FTC situations.

The Observable Case

The following model originated in Ref. 11, where the analysis given below appears in

Ref. 12. Suppose an arrival to the system observes the state (i, j) , such that $i \geq 0$ regular customers and $j \geq 0$ premium customers are present. He/she considers whether or not to purchase priority. The value of j does not effect his/her decision: they inflict on him/her a mean queueing time of j/μ , regardless of whether or not he/she purchases priority. Thus, without loss of generality assume that $j = 0$ and remove further reference to that value. It is clear that the larger the value of i , the larger the value of the priority. Priority is valuable not only in order to overtake regular customers, but also in order not to be overtaken by customers who would arrive in the future and would elect to purchase priority. Thus, one also bears in mind the purchasing strategies used by others, making this decision model a noncooperative game.

Suppose all use the pure threshold strategy of n , namely they purchase priority if and only if they see n or more regular customers upon arrival. Clearly, when all behave like that, n is the largest possible length of the regular queue. Let $W(n)$ be the mean queueing time (exclusive of service) ahead of a customer who is currently in position n in the regular customer queue where the premium queue is empty. Note that $W(n) + 1/\mu$ is his/her mean total time in the queue. Let B be the mean length of a busy period in an M/M/1 queue. Of course, $B = 1/(\mu - \lambda)$.

Theorem 1. *The pure threshold strategy n , $n \geq 1$, is an equilibrium if and only if*

$$\theta - CB \leq CW(n) \leq \theta. \quad (4)$$

¹⁰The interested reader is referred to Ref. 2, p.84, where it is shown that the equilibrium under p_e suffers from lack of stability (defined there) while the two pure equilibria are stable.

Proof. Two conditions need to be met in order for n to prescribe an equilibrium. First, an arrival facing $n - 1$ regular customers, not purchasing priority, and hence having to be in the system for time whose mean equals $W(n) + 1/\mu$ is better than purchasing priority and being there for a time whose mean is $1/\mu$. For that it is required that $CW(n) \leq \theta$. Second, an arrival facing n regular customers, purchasing priority and hence having to be in the system for time whose mean is $1/\mu$ is better than not purchasing priority and having to be in the system for a time whose mean is $B + W(n) + 1/\mu$. Note that the term B here is due to the fact that when all adopt the threshold strategy n , it requires a busy period to move from position $n + 1$ to position n in the regular queue. For this to be an optimal move, it is required that $\theta \leq C(B + W(n))$.

In Ref. 12 it is shown that there exists at least one value for n , which meets inequality 4. Equally important is that it is possible that there are a few consecutive values for such n , leading to multiple equilibria. As stated, this is typical for FTC situations as exemplified, already, in the unobservable version of this problem. Indeed, the larger the threshold used by others (namely, the less aggressive they are in terms of purchasing priority), the larger (i.e., less aggressive) should be the optimal threshold used by an individual, since the risk of being overtaken is now smaller. This intuitive argument is proved to be correct in Ref. 13. It is also shown there that if both n and $n + 1$ prescribe an equilibrium, then there exists another equilibrium, one which mixes between these two thresholds. Under such mixing the mean queueing time of the one in the worst possible position in the regular queue (under this policy) equals θ/C .¹¹ Finally, in Ref. 13, an efficient algorithm for computing the required mean queueing times is developed.

How Much to Pay for an Upgrade

We now look at a different scenario as suggested in Ref. 14. We assume an unobservable

¹¹Yet, as opposed to the pure equilibria, the mixed ones are not stable.

M/M/1 queue where customers are allowed to pay any amount they wish. The more they pay, the higher is their priority level, regardless of how much more they have paid or when they actually have arrived. We assume no preemption and hence the next to commence service among those in line is the one who paid the most. As in the previous section, the option of not joining does not exist.¹² Ties in payments are broken on an FCFS basis. Looking for a Nash equilibrium, it is clear that no pure one exists. Indeed, if all pay the same amount, we end up with an FCFS system. Yet, given this behavior, an individual better pay a bit more and overtake all others. By the same token, the mixed equilibrium should be without atoms. Again, had an atom existed, say at x , one who pays a little bit more than x , would overtake the quantum who pays x . Finally, the support of the values paid is a continuous interval. This is the case since had there been a gap, say in $[a, b]$ with values no one selects, it would have been better paying a than a bit more than b since it comes with a clear saving without actually losing any priority value. This contradicts the fact that all pure strategies in the support come with the same gain. In fact, the support should be $[0, u]$ for some value for u .

A customer who uniquely gets top priority queues up for time whose mean equals ρ/μ . On the other hand, the corresponding value for a customer who is uniquely most inferior equals $\rho/[\mu(1 - \rho)^2]$.¹³ Hence,

$$u' \equiv \frac{\rho C}{\mu(1 - \rho)^2} - \frac{\rho C}{\mu}$$

is an upper bound on the value of priority. Thus, $u \leq u'$. In fact, we next argue that $u = u'$: the one who pays zero (and is uniquely inferior to all) and the one who pays u (and is uniquely prior to all) share the same utility.

¹²For the case where this option exists and all customers share the same value for service R , see Ref. 15.

¹³Proof: A busy period comes with a mean value of $1/[\mu(1 - \rho)]$. Upon arrival, the expected number of customers in the system is $\rho/(1 - \rho)$. The product of these two values is the mean time of what this inferior customer has to spend in the queue.

Had $u < u'$, it would have been better for the former to pay a bit more than u rather than pay zero. Hence, $u = u'$.

The question that remains now is what is the distribution over payments on $[0, u]$ defining the equilibrium strategy. Its cumulative distribution function was derived in Ref. 14. Specifically, let $F(x)$ be the probability of paying up to x . Then, for any $x \in [0, u]$,

$$F(x) = \frac{1}{\rho} \left[\left(\frac{1}{(1-\rho)^2} - \frac{x\mu}{C\rho} \right)^{-\frac{1}{2}} - (1-\rho) \right].$$

In the above model it is assumed that if one pays more than another, regardless of how much more, one has priority over the other. An alternative model, with a relative priority flavor, is suggested in Ref. 16. Specifically, if upon service completion there are n customers in queue and customer i paid $x_i \geq 0$ toward priority, then customer i is the next to commence service with probability $x_i / \sum_{j=1}^n x_j$, $1 \leq i \leq n$. It is shown there that a unique equilibrium exists. Moreover, it is pure and all pay

$$\frac{\rho^2 C}{\mu(1-\rho)(2-\rho)}.$$

TO RENEGE OR NOT TO RENEGE

The phenomenon of customers who renege (abandon) the queue some time after joining, is common. The terminology of reneging hints to the possibility that customers “walked away from a commitment” or that they “change their mind”. Standard modeling does not allow for this possibility. Instead, we assume that customers join the queue while planning to leave it (abandon) later in case that something occurs or some relevant information is revealed to them.

Before giving further details on the model we pose, we make the following observation. In an unobservable M/M/1 FCFS queue, reneging is not due to learning while waiting that the queue length is in fact longer than anticipated. It was shown in Ref. 13, that irrespective of the reneging policy employed by the others, for an individual, the longer

is his/her past waiting time, the shorter is his/her expected time ahead. Thus, if one did not renege until now, it will be inconsistent from one’s side to do it now (or later). Thus, reneging needs to be attributed to increasing waiting costs per unit of time (which can be interpreted as loss of patience) or due to a deterioration in the value of service. In fact, these two factors are two sides of the same coin: the cost/reward ratio should go up while waiting in order to observe reneging.

We next describe two such situations in the unobservable M/M/1 FCFS queue. In the first, when the cost/reward is constant for some time and then it jumps abruptly so as to enforce immediate reneging. Interestingly, no reneging takes place ahead of this time. Yet, one may elect not to join at all. In the second, we let the cost/reward ratio go up smoothly, leading to a mixed equilibrium strategy regarding when to abandon the queue. Thus, reneging can take place at some continuous interval of time after waiting.

The Bang Bang Case

The model we deal with here is as our standard unobservable M/M/1 FCFS model with one key distinction: for anyone who has already stayed T units of time in the system without completing service (regardless of whether it had commenced or not), the value of service drops to zero. Assuming that customers recall the length of their past queueing time (i.e., each one of them holds a watch), a pure strategy here tells whether or not to join, and in the latter case, if and when to renege. As always, mixing is possible. In Ref. 13, it is shown that under any behavior of other, if a best response prescribes joining (not necessarily uniquely), then reneging after waiting for less than T units of time is never part of the best response. This is due to the fact that the probability of completing service in the next instant of time, goes up with the length of the past waiting time. Thus, in our quest for an equilibrium strategy we need to look for an equilibrium joining probability, while it is clear that one who joins reneges after T units of time if service is not completed by then.

In summary, the problem we face here is of finding the equilibrium joining probability.

Let $f(p)$ be the expected utility of one who joins and plans to leave after T units of time if one's service does not end by then, given that all others do the same with probability p (and do not join at all with probability $1 - p$). In Ref. 13, it is shown that

$$f(p) = \frac{R(\mu - \mu e^{-(\mu-\lambda p)T}) + \frac{\lambda p C T (\mu - \lambda p) e^{-(\mu-\lambda p)T} - C \mu (1 - e^{-(\mu-\lambda p)T})}{\mu - \lambda p}}{\mu - \lambda p e^{-(\mu-\lambda p)T}}.$$

Since $f(p)$ is monotone decreasing with p , if $f(1) \geq 0$, then joining (and then reneging at T) is a dominant strategy. Otherwise, there exists a unique value for p , $0 < p < 1$, with $f(p) = 0$. Denote this value by p_e . Then joining with probability p_e (and in case of joining, reneging after T units of time) is the unique equilibrium strategy. Again, this is a ATC situation.

Smooth Deterioration in Waiting Conditions

We now relax the assumption that the cost of waiting per unit of time is constant. So assume that $c(t)$ is the cost of waiting per unit of time for one who already waits t units of time. In other words, one who has already waited for t units of time suffered, so far, a loss of $\int_{\tau=0}^t c(\tau) d\tau$. The situation here is of course more complicated than the one described in the previous section. We describe one possibility as reported in Ref. 17.

Theorem 2. *Assume the following:*

1. $c(0) = 0$ and $c(t)$ is monotone increasing and concave. Also, $\lim_{t \rightarrow \infty} c(t) > R\mu$. Let T_2 be with $c(T_2) = \mu R$.¹⁴
2. $\beta(t) \equiv c(t)/R - c'(t)/c(t)$ is monotone increasing.
3. Let T_1 be with $\beta(T_1) = \mu - \lambda$ and assume that $T_1 < T_2$.

¹⁴It is clear that all renege not later than T_2 units of time after joining.

Define the cumulative distribution function $G(t)$ by¹⁵

$$G(t) = \begin{cases} 0, & 0 \leq t \leq T_1 \\ 1 - \frac{\mu - \beta(t)}{\lambda}, & T_1 \leq t < T_2 \\ 1, & t \geq T_2. \end{cases}$$

Then, the unique equilibrium strategy is to join and then to renege after time which follows the distribution defined by the function $G(t)$.

In Ref. 17, it is also shown that if a pure equilibrium reneging strategy exists (of course, under different assumptions than those postulated Theorem 2), it prescribes reneging at time T_2 . Sufficient conditions for this to be the case are stated there.

CONCLUDING REMARKS

A number of decision problems faced by customers in a memoryless single server queue were surveyed here as noncooperative games. This survey is by no means exhaustive. Other problems were dealt with in the literature. For example, in an M/M/1 when customers never learn the queue situation, they can try again and again, hoping to find the server available. These retrials comes with a cost. The question is then when to retry. The case where customers do not recall their past experience and do not even possess a watch, leading to identically, exponentially, and independently distributed intervals between consecutive retrials, was solved in Ref. 18. The cases of full or partial information regarding their own whereabouts (such as when they have retried last) are still open. Another question is when to arrive (given a finite period and a distribution on the number of arrivals during that period). See Ref. 19 for further details.

The assumption of stationary or steady-state conditions assumed throughout this survey, is removed in Ref. 20. Here customers know their time of arrival and need

¹⁵Note that since $c(T_2) = \mu R$, there is an atom of size $c'(T_2)/(R\lambda\mu)$ at T_2 .

to decide if to try to get service or to leave for good upon arrival to an M/M/N/N queue (when trials are costly and hence finding all servers busy after trying ends up with a loss). Assuming an empty queue at time $t = 0$, the equilibrium strategy prescribes trying if the time of arrival is smaller than some threshold value t_e . Afterwards, one tries with some time-dependent probability $p_e(t)$. Interestingly, $p_e(t_e+) < 1$. Treating similar models, for example the simplest M/M/1 to queue or not to queue model dealt with throughout this survey, is still open. Clearly it is a technically challenging problem.

For more problems dealing also with general service distributions, heterogeneous customers, and multiserver queues see Ref. 2. In particular, see Refs 21 and 22 for the observable version of the “to queue or not to queue” problem in the M/G/1 case.¹⁶

Finally, many models where *informational externalities* are involved can be designed. One example is dealt with in Ref. 23. There, a customer who joins one out of two queues sends, just by his/her own action, a message to future arrivals that this is the better queue to join according to his/her belief. Hence, it sometimes makes sense to join the longer queue. Another example appears in Ref. 24. Here, there is only one server whose utility is not known. Customers get private signals and after inspecting the queue length, decide if they prefer joining over balking. Here too, those who join affect the posterior on the value of service assessed by future arrivals. Again, longer queues can sometimes be more appealing than short ones.

STRUCTURAL RESULTS FOR POMDPs

LUDMILA V. ZHELTOVA

Cleveland State
University, Cleveland,
Ohio

The partially observable Markov decision process (POMDP) is a powerful mathematical model for decision making under uncertainty. A wide range of problems such as inventory control, machine maintenance, quality control, optimal search efforts, and medical decision making could be modeled as POMDP.

POMDP is a generalization of a Markov decision process (MDP). In MDP, the state of the system is known with certainty. However, in POMDP, the underlying state cannot be directly observed. Instead, a belief state, probability distribution over the set of possible states, based on a set of observations and observation probabilities, is used to track the system state.

Owing to its complexity, a primary goal of POMDP analysis is to determine conditions under which the optimal policy has a simple structure. Examples of such policies with simple structures for POMDPs include (i, I) maintenance policy [1], control limit policy (CLP) in maintenance [2–6] and health care [7], and monotone, at-most-four region (AM4R) policy in maintenance [8–13].

A partial order of belief states is necessary in establishing the optimal policy structure. In this article, we discuss two types of partial orders: stochastic and likelihood ratio. The likelihood ratio order of belief states is preserved after conditioning on any information and along with other conditions provides monotonicity of POMDP's optimal value function and policy.

The rest of the article is organized as follows: In the section titled “Model Description”, we formulate general POMDP model.

The section titled “Structured Policies” introduces structural policies and discusses the sufficient conditions for monotonicity of the value function and optimal policy. The section titled “Structured Policies in Maintenance Optimization” discusses in detail the structured policies in the context of maintenance optimization problems when three actions replace, operate, inspect are available.

Lastly, in the section titled “Conclusion”, further reading is outlined.

MODEL DESCRIPTION

Formally, a discrete-time POMDP is defined as a tuple (S, O, A, q, T, R) , where $S = \{0, 1, \dots, N\}$ is a finite set of core states with natural order; $O = \{1, \dots, M\}$ is a finite set of observations; A is a finite set of actions; q is an observation model that specifies the probability of making an observation k in a state $i \in S$; T is a state-transition model that specifies a probability distribution over the resulting state j , given an initial state i and action a ; C is a cost function that maps each underlying state-action pair into an immediate expected cost.

At each decision epoch t , the system is in some state $i \in S$. Although the state i is not directly observable by the decision maker, the probability that the system is in a given state can be calculated. Let π be a vector of state probabilities called a *belief* or *information state*. The belief state π has components $[\pi_0, \pi_1, \dots, \pi_N]$, where π_i is the probability that the system is in the core state i . These belief states form the belief state space $\Omega = \{\pi : 0 \leq \pi_i \leq 1, \sum_{i=0}^N \pi_i = 1\}$.

At each decision epoch t , the decision maker chooses an action $a \in A$ for which the system incurs the immediate expected cost $C(i, a)$ and makes a transition to a new unobservable state $j \in S$ according to a transition probability matrix $p^a = [p_{ij}^a]$, $i, j = 0, 1, \dots, N$. The decision maker receives the observation message k with probability $q_{ij}^a = \Pr\{k | j, a\}$ and updates the new belief state as $T_j(\pi | a, k) \equiv \pi_j(t+1) = \frac{q_{jk}^a(\pi P^a)_j}{\sigma(k | \pi, a)}$, where

probabilities q_{jk} are elements of observation matrix Q and $\sigma(k|\pi, a) = \sum_{i=0}^N q_{ik}^a (\pi P^a)_i$, with $i, j = 0, 1, \dots, N$ and $k = 1, 2, \dots, M$.

To solve POMDP means finding a rule for selecting actions, that is, a policy. Policy optimizes an objective of the process performance. For some problems, as we consider in this article, such an objective is to minimize the total expected discounted cost over an infinite horizon, $V(\pi)$:

$$V(\pi) = \min_{a \in A} \left\{ \sum_{i=0}^{i=N} \pi_i C(i, a) + \alpha \sum_{k=0}^M \sigma(k|\pi, a) V[T(\pi|a, k)] \right\}, \quad (1)$$

where $\alpha \in (0, 1)$ is a discount factor. Let $h(\pi, a) = \sum_{i=0}^{i=N} \pi_i C(i, a) + \alpha \sum_{k=0}^M \sigma(k|\pi, a) V[T(\pi|a, k)]$.

STRUCTURED POLICIES

The policy for a POMDP specifies the actions for all possible belief states. However, solving POMDP, that is, computing the optimal policy, is considered a very hard problem due to continuity of the belief state space (see ‘‘Reduction of a POMDP to an MDP’’). More precisely, a POMDP is considered to be PSPACE-complete, meaning that it ‘‘can be computed using polynomial

space.’’ Numerous exact and approximation algorithms [14–26] exist to solve POMDP, but such an approach to policy computation could have limitations in terms of policy quality and computational efficiency.

Notably, classes of problems with exploitable optimal policy structures can considerably reduce the complexity of POMDP solutions and time required to calculate the optimal policy for particular instance of the problem. *A priori* knowledge of policy structure allows its fast computation and the simplicity of the policy structure provides additional benefits of effective communication and implementation.

It is known that the optimal value function for finite horizon POMDP is piecewise linear and concave function of belief state [24]. The optimal policy for POMDP with three core states and two available actions a_1 and a_2 could be presented graphically as shown in Fig. 1a. Such a policy does not have any structure compare to one that is pictured in Fig. 1b. The policy in Fig. 1b is referred as a *control limit* or *threshold policy*. Since system has three deterioration states, the belief state space Ω is represented by an equilateral triangle, with each point in the triangle corresponding to a belief state. The straight lines presented in both Fig. 1a and b separate sets of belief states where actions a_1 or a_2 are optimal.

Speaking about CLP for MDP, it is defined by the existence of the state i^* such that

Figure 1. Nonstructured and structured POMDP policies for the system with two core states.

action a_1 is optimal in state i if $i \leq i^*$, and action a_2 is optimal for any $i > i^*$, where $i, i^* = 0, 1, \dots, N$. Note that for MDP the system's state is perfectly observable.

In case of POMDP, since the core state is not observable, CLP is defined by specifying the belief state π^* such that for the system in any belief state $\pi \in \Omega$, action a_1 is optimal if π is “smaller” than π^* and action a_2 is optimal if π is “larger” than π^* .

While for MDP, the state order is straightforward, for POMDP belief state is a probability vector and to specify when one belief state is “smaller” or “larger” than the other requires special approach. Particularly, two partial orders of belief states—stochastic and likelihood ratio—are used to define which belief state is “smaller” or “larger” than the other. These partial orders play an important role in establishing the structural results for POMDPs. We define that the belief state π^1 to be stochastically smaller than belief state π^2 , that is, $\pi^1 \prec_{st} \pi^2$, if and only if $\sum_{i=m}^N \pi_i^1 \leq \sum_{i=m}^N \pi_i^2$ for all $m = 0, 1, 2, \dots, N$. We define that the belief state π^1 to be likelihood ratio smaller than the belief state π^2 , that is, $\pi^1 \prec_{lr} \pi^2$, if and only if $\pi_i^1 \pi_j^2 - \pi_j^1 \pi_i^2 \geq 0$ for all $i \leq j$ and $i, j = 0, 1, \dots, N$. It is well known that for $N = 1$, these two partial orders are equivalent and, for $N > 1$, likelihood ratio order implies stochastic order ([27]).

Although, some results on policy structure for POMDPs are achieved by considering stochastically ordered belief states (for example, in Refs 9,13, Lovejoy in Ref. 27 argues that only likelihood ratio order could provide general results for the optimal policy and value function monotonicity because of the fact that likelihood ratio order of belief states is preserved under Bayesian update. That is, for $\pi^1 \prec_{lr} \pi^2$, $T(\pi^1 | a, k) \prec_{lr} T(\pi^2 | a, k)$, if and only if $\pi^1 P^a \prec_{lr} \pi^2 P^a$, for any $a \in A$ and $k \in O$. Likelihood ratio order “survives” the action and observation updates as well, that is, $T(\pi^1 | a, k)$ is likelihood ratio order nondecreasing in $a \in A$ and $k \in O$.

The steps required to establish the optimal policy monotonicity are articulated in Ref. 27. First, the conditions under which the optimal value function is monotone in likelihood ratio ordered belief states must

be found [4]. These conditions include a nondecreasing in core state of the system cost structure, total positivity of order 2 of transition probability and observation matrices. When matrix is totally positive of order 2 (TP_2), if all of its 2×2 determinants are nonnegative. However, the weaker than TP_2 conditions that could be imposed on observation matrices still provide the optimal value function monotonicity along with previously mentioned conditions are possible [27]. The conditions that provide the optimal policy monotonicity on any partial order are established [27] and supermodularity of function $h(\pi, a)$ are included. That is, the optimal policy is monotone along partially ordered sets of belief states, if $h(\pi, a)$ has isotone differences on $\Omega \times A$, that is, $h(\pi^1, a) - h(\pi^1, a') \leq h(\pi, a) - h(\pi, a')$ for $\pi \prec_{lr} \pi^1$ and $a' \leq a$. While details and conditions that provide super/submodularity of the function are omitted [4,28], we would like to note that it arises in many applications and has an interesting property to be preserved under some useful operations such as maximization or minimization.

Finally, sufficient conditions that provide convexity of policy regions and, hence, the monotonicity of the optimal policy are established and discussed in Ref. 29 in detail.

STRUCTURED POLICIES IN MAINTENANCE OPTIMIZATION

In this section, we discuss the conditions that guarantess optimal policy structure in the context of maintenance optimization problem. Consider a production system with a finite set of core states $S = \{0, 1, \dots, N\}$ with state 0 being the “good as new” state and state N being the most deteriorated state for which at each decision epoch three actions are available: replacing the system with a new one, operating the system without inspection, operating with perfect inspection. Further on, we refer to these actions as replacing, operating, and inspecting, respectively. The core state of the system is not observable unless the decision maker is willing to pay for cost l_i , perfect inspection.

Each action takes one time period with C_i , L_i , and $L_i + M$ being per-period replacing,

operating, and inspecting costs, respectively, that the system accrues in core state i , $i = 0, 1, \dots, N$. Then Equation (1) could be specified as follows:

$$V(\pi) = \min \left\{ \begin{array}{l} \pi C + \alpha V(e_0), \\ \pi L + \alpha V(\pi P), \\ \pi L + M + \alpha \pi P V(e) \end{array} \right\}, \quad (2)$$

where $V(e) \equiv [V(e_0), V(e_1), \dots, V(e_N)]^T$ and e_i is a vector with 1 in i th place and 0 everywhere else.

For problem described by Equation (2), the optimal policy structure has been examined in Refs 9, 11–13.

In Ref. 12, Ross considers the system with two core states 0 (“good as new”) and 1 (the worst state). Then the belief state of the process is a probability distribution $\pi \equiv [1 - \pi_1, \pi_1]$, where π_1 is a probability of being in the worst state. He assumes that the cost of operation increases with the deterioration level, while the costs of replacement and inspection are independent of the core state. To establish a policy structure, he considers the cost of operation being less than the cost of inspection and less than the cost of replacement and the transition probability matrix P being upper-triangular. These conditions allow to define the optimal policy as monotone, AM4R policy, that is, there exist three numbers p_1 , p_2 , and p_3 , where $0 \leq p_1 \leq p_2 \leq p_3 \leq 1$, such that it is optimal to replace the system if $p_3 \leq \pi_1$, to inspect the system if $p_1 \leq \pi_1 < p_2$, and to continue to operate otherwise. The numerical example illustrating this policy structure could be found in Ref. 12. Such a policy could be graphically presented as four disjoint regions (Fig. 2). The existence of the second operate region is somewhat counterintuitive, but could be explained by the reasoning that in the current state, it might not be worth inspecting the system that is about to be replaced.

In Ref. 13, White extends the results of Ref. 12 for an $N + 1$ state system such that the more that the system deteriorates, the more likely it is to deteriorate further. White establishes conditions under which the optimal policy has monotone, AM4R structure along the straight line of stochastically increasing belief states. These conditions include nondecreasing in core state-action costs with operating costs increasing faster than replacement costs.

Next, conditions that provide monotone, AM4R policy structure along sample path are established in Refs 9 and 11. We define the sample path as a sequence of belief states that the process would occupy over time if the system operates continuously and no actions are taken. For example, the sample path emanating from belief state π is $\{\pi, \pi P, \pi P^2, \dots\}$.

Assuming that transition probability matrix P is upper-triangular and TP_2 , and the same cost structure as in Ref. 13, Rosenfield establishes the monotone, AM4R structure along sample path that emanates from state e_i , $i = 0, 1, \dots, N$.

The assumptions about transition probability matrix P are of a particular interest. Upper triangularity of the transition probability matrix implies that the system could not improve on its own and TP_2 ness of this matrix implies that the more the system deteriorates, the more likely it is to deteriorate further. Note that these conditions imposed on matrix P yield likelihood ratio order increasing sample paths, that is, $e_i \prec_{lr} e_i P \prec_{lr} \dots \prec_{lr} e_i P^k$.

Finally, the results providing monotone, AM4R optimal policy structure, received in Ref. 11, are extended in Ref. 9 for the certain time-based sample paths.

If we consider the sample path emanating from any belief state π , then in order for this path to be in increasing likelihood ratio order,

Figure 2. Monotone, AM4R policy for the system with two core states.

this path, first, should start in increasing likelihood ratio order and, second, stay in this order. While the latter is provided by the TP_2 ness of transition probability matrix P , the former requires state π to belong to a special region defined as $\Omega_{\ell r} \equiv \{\pi \in \Omega : \pi \prec_{\ell r} \pi P\}$.

Although one could argue that the system mostly starts from the known state or returns to a known state after the replacement or inspection, it is still worthwhile to establish policy structure along nonextreme sample paths in order to gain insights that might be useful in establishing similar results for systems with imperfect information.

Furthermore, interesting results concerning monotone, AM4R policy structure for maintenance optimization problems could be found in Refs 1,8,10, and 30.

CONCLUSION

This article introduces the structural results for POMDP and discusses the conditions that provide such results for general POMDP model.

In this article, we discuss in detail the monotone, AM4R policy structure and conditions that guarantee such a structure for a particular maintenance optimization problem. However, CLPs are subject of numerous papers in different areas of research. Interested reader could find the results concerning CLPs in Refs 3,31–33. Though, we consider only stochastic and likelihood ratio partial orders, some papers consider different partial orders. For example, in Ref. 34, results concerning policy structure are achieved by considering Blackwell partial order.

Interested reader could find further details about maintenance policies in Refs 35–38. Also, Monahan in Ref. 19 provides an excellent overview of POMDP models including some structural results.

Provence), France

MONOTONIC OPTIMAL POLICIES

The structure of optimal policies and/or of the value function can be used to reduce the original Markov decision process (MDP) to an optimization problem over a smaller subset of policies, namely the *structured ones*. Monotonicity of optimal policies is a well-known and useful structural property (Chapter 8 in [1], p. 368; Section 4.7.3 in [2], p. 105). It reduces the exponential growth in the dynamic programming (DP) formulation with respect to the size of an MDP, when looking for the optimal policies. It also often allows for feasible numerical solutions ([3], Section 7.9 in [4], p. 210).

Recently, the structure of the value function has been used to compare different control systems (Chapter 11 in [5], p. 61).

This article focuses on monotonic optimal policies for maximization of MDPs (see **MDP Basic Components**). It is mainly based on the monotonicity research of [6–8]: set using DP and with monotonicity entailed by the objective function shown to be supermodular/submodular. Thus, the DP algorithm proves to be useful for the theoretical investigation of the structure of the control problems. For other general approaches see [1,9–12].

The monotonicity of an optimal policy reflects the qualitative properties of the problems studied. For monotonicity we need partially ordered state and action spaces. Partial orderings are important in many fields, and have spread out from mathematics

to physics, biology, and economics. In physics, partial ordering stands beside spatial symmetries and Hamiltonian structures for dynamical systems studies; these being properties that induce specific behaviors. As pointed out in [13], partial orderings significantly restrain the behavior, yet allow for interesting (and even chaotic) trajectories.

Partial orderings affect the chaotic behavior. They avoid it for most initial conditions or they make it unstable when physically observing the system in the long run. This type of robustness is also discussed for monotonic optimal policies. Partial orderings doubled by the lattice programming techniques of [8] encompass many applications in admission and control of queues, maintenance, production planning models.

Widely known optimal monotonic behavior paths are the threshold policies. Threshold policies (on–off controls) for dynamical systems are strategies that switch the control inputs from one level to another whenever a certain measured variable crosses a predetermined single threshold value. A control limit policy or simple threshold is defined by the existence of a state x_0 such that if the observed state is $x \geq x_0$, then it is optimal to make a change, otherwise it is optimal to continue the current trend. The proof of their optimality was very often made by an induction based on value iteration (see **Total Expected Discounted Reward MDPs: Value Iteration Algorithm**), which establishes a submodular/supermodular type of property for the optimal value function. They were identified early in manufacturing and admission control of queues problems.

Example 1. Simple threshold policy in a two-server queueing system (from [14,15])

Consider a queue with Poisson arrivals (rate λ) and two exponential servers, with asymmetric service rates μ_1 and μ_2 (with $\mu_1 > \mu_2$). The customers in the queue have to be assigned non-preemptively to the servers, that is, a customer sent to the slower server cannot be sent back to the queue. A controller

decides after each event/jump (which can either be an arrival or a service completion) if it sends a customer from the queue to a free server (if available).

Lin and Kumar [14] and Koole [15] studied this model and showed that to minimize the number of customers in the system, the fast server should always be used (as long as there are customers in the queue), and that the slower server should only be used if the number of customers in queue exceeds a certain level. Thus, monotonicity means that if we move a customer to a slower server in the state $(x + 1, 0)$, then we are going to similarly move one in any state $(x + n, 0)$ with $n \geq 1$.

The state space considered was of the form (x, i) where x is the total number of customers in the queue and at the first server, and $i \in \{0, 1\}$ denotes the number of customers at the second server. In [14], $\rho(x, i) = x + i$ is taken as a direct cost, while [15] used a more general class of cost functions, including $\rho(x, i)$.

Assuming, by scaling, that $\lambda + \mu_1 + \mu_2 = 1$, in [15] the continuous-time model was reduced to a discrete one by uniformization (see **Uniformization in Markov Decision Processes**), looking just at the event/jump times. For the moments when one of the servers idles, a fictitious transition was added to make the times between each two jump times identically exponentially distributed. $u_n(x, i)$, the expected cost over the next n jumps, in the embedded discrete-time model, starting in state (x, i) , was defined as:

$$u_{n+1}(x, i) = \rho(x, i) + \lambda w_n(x + 1, i) + \mu_1 w_n((x - 1)^+, i) + \mu_2 w_n(x, 0); \quad i = 0, 1, \quad \text{where} \\ w_n(x, 0) = \min\{u_n(x, 0), u_n(x - 1, 1)\} \quad \text{if } x > 0, \\ w_n(0, i) = u_n(0, i), \quad w_n(x, 1) = u_n(x, 1), \quad u_0(x, i) = \rho(x, i).$$

The optimality of the threshold policy holds if $u_n(x + 1, 0) - u_n(x, 1) \leq u_n(x + 2, 0) - u_n(x + 1, 1)$. Indeed, if $u_n(x + 1, 0) - u_n(x, 1) \leq 0$, then it is optimal not to use the second server, and vice versa. Thus, as shown in [15], if $u_n(x + 1, 0) - u_n(x, 1)$ is increasing in x , a threshold policy is optimal.

This requirement also eliminated the theoretical possibility of moving a customer from server 1 to 2 (from the definition of $w_n(1, 0)$).

By taking that $\rho(x, i) = g(x + i)$, with g increasing and convex, both the supermodularity of u_n and the desired monotonic increase were obtained.

Other types of threshold policies are the start up policies, N-policies, D-policies, T-policies (see Chapter 11 in [1], p. 444) for the single removable server and known workload with a $M/G/1$ queue or $M^X/G/1$ queue with batch arrivals. Under the N-policy, the server idles each time the system becomes empty, that is, there is no customer in the system and the server activates itself when there are N customers in the system. The D-policy activates the server when the cumulative service times of the customers in the queue exceeds some fixed value D . Under the T-policy the server can take a vacation time T after the system becomes empty. If there are no customers at the end of the vacation, the server takes another vacation. If customers are found, the server is activated (turned on) and works until the system is empty. See [16]; Chapter 11 in [1], p. 448 for a detailed discussion.

In general under a monotonic optimal policy, the decision increases with the state of the system. This means that the greater the rank of a state is (in the state space order), the higher its impact will be. The classical examples of simple monotonic policies are optimal pricing of a single product based on sales, optimal advertising of a single product based on sales, and optimal maintenance with overhaul options of one unreliable machine. For details see Chapter 3 in [8], p. 167 and Chapter 4 in [17], p. 108. Under a series of conditions, which will be discussed in this article, the monotonic policies can be described as: “As sales decreases in the current period, it is optimal to advertise more in the next period.”, “Optimal prices in each period increase with the sales in the preceding period.”, “More radical overhaul operations are taken when the machine is in a less desirable state.”

The rest of this article is structured as follows. The second section presents generalities regarding lattices, as well as some of Topkis’s results concerning maximization of supermodular functions on lattices.

The third section presents monotonicity results for discrete-time MDP models with finite and infinite horizons, as well as for partially observed Markov decision processes (POMDPs). The fourth section gives comparable statistics for the optimal monotonic nondecreasing policies. The fifth section presents monotonicity results for continuous-time models. The sixth section succinctly presents the relationship between supermodularity and convexity, as well as ways of obtaining other types of structured policies. Finally, the seventh section presents some interesting classes of monotone policies encountered in applications.

LATTICE PROGRAMMING TECHNIQUES PRELIMINARIES

Definition 1. A set X endowed with a reflexive, antisymmetric, and transitive binary relation “ $\leq_X$ ” on X is called a partially ordered set (poset).

Definition 2. Let $(X, \leq_X)$ be a finite poset. An antichain (respectively, chain) in X is a set of pairwise incomparable (respectively, comparable) elements. The size of the longest antichain (respectively, chain) is called the partial order width (respectively, length). A chain C is called complete in X if for any $x, y \in C$ such that $x \leq_X y$, $\nexists z \in X \setminus C$ such that $x <_X z <_X y$.

Lemma 1 [Dilworth’s Lemma and its Dual [18,19]]. *The partial order width of a finite poset $(X, \leq_X)$ is equal to the minimum number of chains needed to cover X . The partial order length of a finite poset $(X, \leq_X)$ is equal to the minimum number of antichains needed to cover X . If N be the cardinality of X , W the partial order width, and L the partial order length then $N \leq LW$.*

In other words, Dilworth’s Lemma states that the nonexistence of an antichain of size $n + 1$ in $(X, \leq_X)$ is a necessary and sufficient condition for $(X, \leq_X)$ to be the union of n total orders. This union provides a visualization

of a finite poset, which allows for a lossless enumeration of its elements.

Example 2. Let $(X, \leq_X)$ be the power set of a finite set $X = \{1, 2, 3\}$ ordered by inclusion. Then the poset width is 3. The antichain description is $\{\emptyset\}, \{\{1\}, \{2\}, \{3\}\}, \{\{1, 2\}, \{2, 3\}, \{1, 3\}\}, \{\{1, 2, 3\}\}$, while the chain description is $\{\emptyset, \{1\}, \{1, 2\}, \{1, 2, 3\}\}, \{\emptyset, \{2\}, \{2, 3\}\}, \{\emptyset, \{3\}, \{1, 3\}\}$.

Definition 3. Let K a subset of a poset $(X, \leq_X)$ and $x \in X$. We say that x is an upper bound (respectively, lower bound) of K , denoted by $x \geq_X K$ (respectively, $x \leq_X K$), if for all $y \in K$, we have $x \geq_X y$ (respectively, $x \leq_X y$).

Definition 4. A lattice is a partially ordered set $(X, \leq_X)$ where for any pair of elements there is a supremum (least upper bound) and infimum (greatest lower bound) (belonging to X). Let $Y \subseteq X$ a subset in the lattice. Then Y is a complete sublattice of X if for any $a, b \in Y$, both their maximum (denoted by $a \vee b$), and their minimum (denoted by $a \wedge b$) taken in X are elements of Y .

Definition 5. In the vector-lattice $(X_1 \times \dots \times X_N, \leq_{X_1}, \dots, \leq_{X_N})$ we say that $x, y \in X_1 \times \dots \times X_N$ are in the natural order relation “ $x \leq y$ ” if componentwise $x_i \leq_{X_i} y_i, \forall i \in \{1, \dots, N\}$.

Figure 1. Representation of a vector-lattice $X \times Y$ as a set of antichains—layers, each of them in turn is also represented as a union of antichains according to $\leq_X$.

Figure 2. Representation of the vector-lattice obtained from the product with itself of the powerset of $\{1, 2\}$ ordered by inclusion.

Using Dilworth's Decomposition Lemma (i.e., Lemma 1) a vector-lattice $X \times Y$ can first be $\leq_{X \times Y}$ -decomposed and then any antichain can be further $\leq_X$ -decomposed—see Fig. 1. We notice that a complete chain in $X \times Y$ contains an element from each horizontal layer of the graphic decomposition of the lattice $X \times Y$.

Example 3. For the product with itself of the powerset of $\{1, 2\}$ ordered by inclusion we have Fig. 2.

Definition 6. Let $(X \times Y, \leq_{X \times Y})$ be a vector-lattice and $Z \subseteq X \times Y$. We say that Z is a subset without holes if for any $(x, y), (\tilde{x}, \tilde{y}) \in Z$, Z includes all the minimal length complete chains containing elements $(a, b) \in X \times Y$ such that $(x, y) \leq_{X \times Y} (a, b) \leq_{X \times Y} (\tilde{x}, \tilde{y})$.

Definition 7. Let $(X \times Y, \leq_{X \times Y})$ be a vector-lattice and $Z \subseteq X \times Y$ a subset. Then $\mathbf{Bot}(Z)$ is the bottom of Z if any $y \in \mathbf{Bot}(Z)$ is such that $\nexists x \in Z$ with $x < y$ (i.e., a minimal element of Z) and any two elements of $\mathbf{Bot}(Z)$ are not comparable. Likewise, by reversing the order we define that $\mathbf{Top}(Z)$ is the top of $Z \subseteq X \times Y$.

Definition 8. A subset K of a poset $(X, \leq_X)$ is said to be increasing if $x \in K, \tilde{x} \in X$ and $x \leq_X \tilde{x}$ implies $\tilde{x} \in K$.

Lemma 2 [Theorem 2.3.1 from [8], p. 30]. A sublattice of $\mathbb{R}^n$ is subcomplete if and only if it is compact.

Definition 9. Let X, Y be posets. A function $g : X \times Y \rightarrow \mathbb{R}$ is supermodular (sometimes called superadditive) on $X \times Y$ if it satisfies: $g(x^+, y^+) + g(x^-, y^-) \geq g(x^+, y^-) + g(x^-, y^+)$ for any $x^+ \geq_X x^-$ in X , and $y^+ \geq_Y y^-$ in Y (Section 4.7.2 in [2], p. 103). The function $-g$ is submodular if and only if g is supermodular.

Definition 10. Let X, Y be posets. Let $S \subseteq X \times Y$, we say that $S_y = \{x | (x, y) \in S\}$ is the section of S at $y \in Y$.

Definition 11. Let X, Y be posets, $S \subseteq X \times Y$, and S_y the section of S at $y \in Y$. A function $f : S \rightarrow \mathbb{R}$ has isotone or increasing differences in (x, y) on S if $f(x, y^+) - f(x, y^-)$ is increasing in x on $S_{y^-} \cap S_{y^+}$, for all $y^+ \geq_Y y^-$ in Y (Section 2.6.1 in [8], p. 42). A function g has antitone or decreasing differences on S if $-g$ has increasing differences.

For lattices, we also have the following definition, which is consistent with Definition 9:

Definition 12. Let X be a lattice. A function $f : X \rightarrow \mathbb{R}$ is supermodular on X if it satisfies $f(x) + f(\tilde{x}) \leq f(x \vee \tilde{x}) + f(x \wedge \tilde{x})$ for all $x, \tilde{x} \in X$, where $\vee$ denotes the maximum operator, and $\wedge$ denotes the minimum lattice operator (Section 2.6.1 in [8], p. 42).

The following lemma presents a series of properties encountered in the monotonicity proofs for stationary Markov control processes.

Lemma 3. *Let X and A be fixed nonempty Borel subsets of $\mathbb{R}^n$ and $\mathbb{R}^m$, respectively. For each $x \in X$, let A_x be a nonempty (measurable) subset of A . Let $S = \{(x, a) | x \in X, a \in A_x\}$ be a measurable subset of $X \times A_x$.*

Let $v, w : S \rightarrow \mathbb{R}$.

1. *If v and w have isotone/increasing differences, then so has $v + w$.*
2. *Let S be a lattice. If $w(\cdot, \cdot)$ is submodular, then $w(x, \cdot)$ is also submodular, for each $x \in X$.*
3. *Let $w_1 : X \rightarrow \mathbb{R}$ and $w_2 : A \rightarrow \mathbb{R}$, then $w(x, a) = w_1(x) \cdot w_2(a)$ has increasing differences if w_1 is an increasing monotone function and w_2 is a decreasing one.*

From a practical point of view, submodularity and supermodularity can be seen as *complementarity* and respectively *substitutability*. Loosely speaking, when optimizing some cost $f : X$ across features (elements of X), two features are substitutes (respectively complements) when having more of one of them does not induce us to choose more (respectively less) of the other.

Specifically, let us model production costs in an economic system with n kinds of inputs through a function f , supermodular on $\mathbb{R}_+^n$, as in [1], p.377. Suppose all inputs are used as much as possible. If f is supermodular on $\mathbb{R}_+^n$, then

$$f(x + \gamma e_i) - f(x) \leq f(x + \lambda e_j + \gamma e_i) - f(x + \lambda e_j),$$

for $x \in \mathbb{R}_+^n$, $\gamma > 0$, $\lambda > 0$, and $i \neq j$. This inequality states that the extra cost of using γ extra units of input i is raised by having λ extra units of input j (notice that here we have no economies of scale, but the opposite effect). In other words, having more of input j may reduce the effectiveness of using more of input i . In this sense, inputs i and j substitute each other's effectiveness. Thus, in economics, nondecreasing differences, hence supermodularity, are equivalent to commodities being *substitutes*. Similarly, submodularity, is equivalent to commodities being *complementary* (unrelated products or products that might be consumed together).

Sufficient Conditions for Increasing Solutions

In agreement with [7,8], we consider a parameterized collection of maximization problems, which includes the MDPs and stochastic games as particular cases. A stochastic game with only one player is the MDP. A decision rule is an equilibrium point in a one-player stochastic game if and only if it is an optimal policy in the MDP [20].

In this section we state sufficient conditions, in terms of supermodularity and increasing differences, for increasing/isotone optimal solutions. For an exhaustive discussion on lattice programming techniques see [8]. For the alternative minimization formulation we refer to [9] and Chapter 8, Monotone Optimal Policies, in [1], p. 368. The main results of this section are Topkis's Theorem stating the preservation of supermodularity under the maximization operation and Topkis's Theorem describing the argmax sets encountered in the DP framework under submodularity.

Theorem 1 [Topkis's Theorem 2.7.6 from [8], p. 70]. *Let X, A be lattices and S a sublattice of $X \times A$ and $A_x \subseteq A$ for any $x \in X$. If*

1. *$g(\cdot, \cdot) : X \times A \rightarrow \mathbb{R}$ is supermodular in $(x, a) \in (X \times A)$,*
2. *$f() : \prod_X S \rightarrow \mathbb{R}$ is defined by $f(x) = \sup_{a \in A_x} g(x, a)$, where $\prod_X S$ is the projection of S on X .*

Theorem 2 [Topkis's Theorem 2.8.1 from [8], p. 76]. *Let A be a lattice, X be a partially ordered set, and $A_x \subseteq A$ for any $x \in X$. If we have*

1. *A_x is increasing in $x \in X$ ($A_x \subseteq A_{\tilde{x}}$ for $x \leq_X \tilde{x} \in X$)*
2. *$g(x, \cdot) : A \rightarrow \mathbb{R}$ is supermodular in $a \in A$ for each $x \in X$, and has increasing differences in $(x, a) \in (X \times A)$*

then $\arg \max_{a \in A_x} g(x, a)$ is increasing in x on $\left\{x \in X \mid \arg \max_{a \in A_x} g(x, a) \text{ is nonempty} \right\}$.

Lemma 4 *[[21] Extension of Theorem 2 Theorem 2.8.1 from [8], p. 76, and Lemma 4.7.1 from [2], p. 104]. Let X be a poset and let $A := \cup_{x \in X} A_x$ be a poset indexed after X , and $g : X \times A \rightarrow \mathbb{R}$ a real-valued supermodular (sometimes called superadditive) function on $(\tilde{x}, \tilde{a}) \in X \times A_x$, for each $x \in X$, with $g(x, a) = 0$, for any $(x, a) \notin X \times A_x$. If we have*

1. *for each $x \in X$ there exists $\max_{a \in A} g(x, a)$*
2. *$A_x \subset A_{\tilde{x}}$ for any $x \leq_X \tilde{x} \in X$, and $A_x = A_{\tilde{x}}$, for any $x, \tilde{x} \in X$ not comparable (i.e., the family $\{A_x \mid x \in X\}$ is expanding)*
3. *for any $x \leq_X \tilde{x} \in X$ and $a \leq \tilde{a} \in A_x \cup A_{\tilde{x}}$ we have that $a \in A_x$ and $\tilde{a} \in A_{\tilde{x}}$ (i.e., the family is ascending)*

then for any $x^+ \geq_X x^-$ in X , and any $a^- \in \text{Top arg max}_{a \in A_{x^-}} g(x^-, a)$ either there exists $a^+ \in \text{Top arg max}_{a \in A_{x^+}} g(x^+, a)$ such that $a^+ \geq_A a^-$ in A , or there is no element in $\text{Top arg max}_{a \in A_{x^+}} g(x^+, a)$ comparable with a^- .

We notice that the operation “max” returns a value, while “arg max” returns a set. The Top arg max being thus the Top of the set returned by “arg max” according to Definition 7.

DISCRETE-TIME MODELS

Discrete-Time Markov Decision Problems—Definition

The results presented in this section hold for a large class of discrete-time nonstationary Markov control processes with finite horizon and can be easily extended for the infinite horizon.

We consider the following as a discrete-time nonstationary Markov control model with immediate rewards:

$$\mathcal{M} = \left\{ (X(t), A, A_t(x_t), S_t, Q_t(\cdot | x_t, a_t), \rho_t(x_t, a_t))_{t \in \mathbb{N}} \right\}.$$

In all generality the state and action spaces are standard Borel spaces (i.e., nonempty Borel subsets of a Polish space endowed with the σ -field of Borel subsets). We restrict this model to $X(t), A_t(x_t) \subset A$ subsets of $\mathbb{R}^q$ respectively $\mathbb{R}^m$. More general results are stated whenever the case occurs.

The system with state space $X(t)$ is observed at discrete time periods $t = 0, 1, \dots$. When the system is observed at time t to be at state $x_t \in X(t)$, an action a_t from the action set $A_t(x_t)$ should be chosen. Let $S_t := \{(x_t, a_t) \mid (x_t, a_t) \in X(t) \times A_t(x_t)\}$ be the set of possible pairs of state and action at each period. Let $A := \cup_{t \in \mathbb{N}} \cup_{x_t \in X(t)} A_t(x_t)$ be the union of all action sets. After $a_t \in A_t(x_t)$ is chosen, the following two things will happen:

1. the system will receive a reward $\rho_t(x_t, a_t)$ and
2. the system will transfer to state x_{t+1} at the next period. The state transition probability governed by $Q_t(\cdot | x_t, a_t)$, where Q_t is a measurable stochastic kernel on $X(t)$ given S_t ; that is, $Q_t(\cdot | x_t, a_t)$ is a probability measure on the σ -field of Borel subsets of $X(t)$ and $Q_t(B | \cdot, \cdot)$ is a measurable function on S_t for each $B \subset X(t)$.

Several optimality criteria are used to identify a decision-making policy: maximizing the expected total discounted reward over the course of the entire process **Total Expected Discounted Reward MDPs: Existence of Optimal Policies, Total Expected Discounted Reward MDPs: Policy Iteration Algorithm, Total Expected Discounted Reward MDPs: Value Iteration Algorithm**, maximizing the expected total reward or maximizing the average reward **Average Reward of a Given MDP Policy**.

Taking a discount factor into account does not affect any theoretical results in the finite horizon problems, while in the infinite horizon problems it does.

For a finite horizon problem ($T < \infty$) an optimal (deterministic) policy can be found by solving the following set of recursive equations (via backwards induction/DP

algorithm)

$$f_t(x_t) = \sup_{a_t \in A_t(x_t)} \left\{ \rho_t(x_t, a_t) + \lambda \int f_{t+1}(z) dQ_t(z|x_t, a_t) \right\}, \quad (1)$$

where $f_t(x_t)$ is the optimal MDP value function in state $x_t \in X(t)$. For discrete space (finite or countable) we use $p_t(x_t, a_t, x_{t+1})$ since $\int f_{t+1}(z) dQ_t(z|x_t, a_t) = \sum f_{t+1}(z) P\{Z_{x_t, a_t, t} = z\} = \sum f_{t+1}(z) p_t(x_t, a_t, z)$. The discrete analog of the optimality equations above can be written as

$$u^*(x_t) = \sup_{a_t \in A_t(x_t)} \left\{ \rho_t(x_t, a_t) + \lambda \sum_{x_{t+1} \in X(t+1)} \times p_t(x_t, a_t, x_{t+1}) u_{t+1}^*(x_{t+1}) \right\} \quad (2)$$

for $x_t \in X(t); t = 1, \dots, T-1$.

The above optimality equations are also referred to as *Bellman equations* or *functional equations*. The u^* is sometimes referred as *value-to-go function*.

Passing to the limit in the finite horizon optimality equations we obtain the characterization of an optimal policy that maximizes the expected total discounted reward of a stationary model in the infinite horizon case: $f(x) = \sup_{a \in A(x)} \{ \rho(x, a) + \lambda \int f(z) dQ(z|x, a) \}$.

An optimal policy that maximizes the expected total discounted reward can be found by solving the following set of recursive equations

$$f_i(x) = \sup_{a \in A(x)} \left\{ \rho(x, a) + \lambda \int f_{i+1}(z) dQ(z|x, a) \right\}, \quad (3)$$

where $f_i(x)$ is the optimal MDP value function in state $x \in X$. The optimal action $a^*(x)$ for state $x \in X$ is chosen as the argument $a \in A(x)$ that maximizes the right-hand side of the equation above. Value iteration (see **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**) and linear programming are algorithms used to solve the recursive optimality equations.

Definition 13. Let $\mathbf{D}_t = \{d_t : X(t) \rightarrow A | d \text{ measurable } d_t(x_t) \in A_t(x_t), \forall x_t \in X(t)\}$

be the set of decision rules at time t . Let $\mathbf{D}_t^* = \{d_t^* : X(t) \rightarrow A | d^* \text{ measurable } d_t^*(x_t) = a^*(x_t) \in A_t(x_t), \forall x_t \in X(t)\}$ be the set of decision rules maximizing the Bellman optimality equation (2) at stage t . A nonstationary Markovian (deterministic) policy is a sequence of decision rules, that is, $\pi = \{d_t\}_{t \in \mathbb{N}}$.

1. π is called a monotonic nondecreasing policy if for any $x_t \leq_{\mathbb{N}^q} \tilde{x}_t$ we have $d_t(x_t) \leq_{\mathbb{N}^m} d_t(\tilde{x}_t)$.
2. π is called a weakly monotonic nondecreasing policy if for any $x_t \leq_{\mathbb{N}^q} \tilde{x}_t$ either $d_t(x_t) \leq_{\mathbb{N}^m} d_t(\tilde{x}_t)$, or $d_t(\tilde{x}_t)$ and $d_t(x_t)$ are not comparable (see [22] for the weak order definition).

A stationary (deterministic) Markovian policy is a sequence of decision rules, that is, $\pi = \{d_t\}_{t \in \mathbb{N}}$, with $d_t = d$. It is denoted by d^∞ , and this type of policy is very important for the infinite horizon MDP. A stationary (deterministic) Markovian policy $d_t : X(t) \rightarrow A$ with $d(x) = a^*(x)$ is denoted by $(d^*)^\infty$.

More information on different types of policies can be found in **MDP Basic Components** as well as in Chapter 2 in [2], p. 22. For the optimality of the deterministic stationary policy $(d^*)^\infty$ we refer to Chapter 6, Section 6.2 in [2], p. 146, as well as **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**.

Monotonicity Obtained via Dynamic Programming

To prove a conjectured property of the optimal policies one needs

1. to identify the key structural properties that drive the result (supermodularity in our case) and
2. to prove by induction that these structural properties are inherited from one stage to another in the optimality DP equations.

In the case of monotonic optimal policies, during the second step, one uses the so-called closure properties of the key structural properties. They are maximization preserves

Table 1. Ways of Constructing a Submodular/Supermodular Function

h convex	h concave	v super-modular	v submodular	h decreasing	h increasing	v monotonic	$h \circ v$ super-modular	$h \circ v$ super-modular
X		X			X	X	X	
X			X	X		X	X	
	X	X		X		X		X
	X		X		X	X		X

submodularity and monotonicity, and expectation preserves monotonicity.

The monotonicity of the optimal policies for discrete-time MDPs is generally proven by induction via value iteration. To prove the increasing monotonicity of the optimal policy we first have to prove that at each stage t , a series of properties on the value-to-go (optimal return) function f_t defined by the optimality equations. The method suggested by Topkis's results in the section titled "Sufficient Conditions for Increasing Solutions" is informally the following:

1. Determine the regularity conditions for the existence of an optimal stationary policy for the infinite horizon case.
2. Determine the conditions under which, at an arbitrary stage t , the function f_{t+1} is monotone increasing, and thus the conditions for the optimal decisions increase with the state (Lemma 6) (proof by induction).
3. Define $w_t(x_t, a_t) = \rho_t(x_t, a_t) + \lambda \int f_{t+1}(z) dQ_t(z|x_t, a_t)$ being the immediate reward plus the value-to-go (optimal return) at stage $t+1$ and determine the conditions under which $w_t(x_t, a_t)$ is supermodular in $(x_t, a_t) \in S_t$ (either Theorem 3 or Theorem 4).
4. According to Topkis's Theorem 1, which states the preservation of submodularity under the maximization operation, we establish that $f_t(a_t) = \sup_{a_t \in A_t(x_t)} w_t(x_t, a_t)$ is supermodular. The supermodularity of the optimal return function is thus propagated inductively from stage to stage.
5. $w_t(x_t, a_t)$ being also nondecreasing, we are in the conditions of the Theorem 2, which establishes that the optimal decisions are increasing.

The submodularity of the value-to-go function requires, in most of the cases, the submodularity of the immediate rewards. For a detailed discussion on the propagation of properties via the DP we refer to [23].

Different ways to obtain submodularity conditions had their inspiration in Table 1 in [6], p. 312.

This table gives a variety of ways of constructing a submodular or supermodular function by taking the composition of two other functions with certain properties. In Table 1 we read across any given row, and the assumptions corresponding to the checked columns on the left of the double line imply the result corresponding to the checked column to the right of the double line. All properties of v and $h \circ v$ hold on a given lattice L , v is a real-valued function on L , and h is a real-valued function on the real line.

Definition 14. Let $K \subseteq \mathbb{R}^p$ and $X \subseteq \mathbb{R}^q$, and let $\int_K d\tilde{Q}(z|x)$ be the probability measure of K with respect to the distribution function $\tilde{Q}(z|x)$ on $\mathbb{R}^p$. $\tilde{Q}(z|x)$ is said to be stochastically increasing in x on X if $\int_K d\tilde{Q}(z|x)$ is increasing in x on X for each increasing subset K in $\mathbb{R}^p$.

On the basis of Theorem 3.9.1 in [8], p. 160, [24] on stochastically increasing distribution functions, we have the following Lemma.

Lemma 5 [General form in Theorem 3.9.1 from [8], p. 160, [24]]. Let X a subset of $\mathbb{R}^q$ and $\{\tilde{Q}(z|x)|x \in X\}$ a collection of distribution functions on $\mathbb{R}^p$. $\tilde{Q}(z|x)$ is stochastically increasing in x on X if and only if $\int h(z)d\tilde{Q}(z|x)$ is increasing in x on X for each increasing real-valued function $h(z)$ on $\mathbb{R}^p$.

Further reading on stochastic orderings is in [10,25,26]. In [27] integral stochastic orderings are used to prove the monotonicity

of optimal value functions. Their model has general state and action space and is a finite horizon, discrete time one. However, using [28] it can be extended to the infinite horizon case. In the case of convex order, see also [29,30].

Lemma 6 [Lemma 3.9.4. from [8], p. 164]. *Consider a discrete-time nonstationary Markov decision process with finite horizon T . If for any $t \in \{0, 1, \dots, T-1\}$, $\lambda \in (0, 1)$,*

1. $A_t(x_t) \subset A_t(\tilde{x}_t)$ for any $t \in \{0, 1, \dots, T-1\}$ and all states $x_t \leq_{\mathbb{R}^q} \tilde{x}_t \in X(t) \subset \mathbb{R}^q$
2. $\rho_t(\cdot, a_t), \rho_T(\cdot) : X(t) \rightarrow \mathbb{R}$ are non-decreasing in x_t , for any $(x_t, a_t) \in X(t) \times A_t(x_t)$
3. the distribution function for the state w in the period $t+1$ given the state x and the action a , $Q(w|x_t, a_t)$, is stochastically increasing in x , for any $(x_t, a_t) \in X(t) \times A_t(x_t)$.

Then the maximizer $f_t(\cdot) : X(t) \rightarrow \mathbb{R}$ is nondecreasing for any $t \in \{0, 1, \dots, T\}$ where

$$f_t(x_t) = \max_{a_t \in A_t(x_t)} \left\{ \rho_t(x_t, a_t) + \lambda \int f_{t+1}(z) dQ_t(z|x_t, a_t) \right\}.$$

The key element of the proof of Lemma 6 is Lemma 5.

Example 4. Maintenance with overhaul [Example 3.9.5. from [8], p. 168]. Consider a firm operating an equipment whose state $x \in \mathbb{R}^q$. A higher value of x indicates a more desirable state, as it is made more precise below. The firm can partially control the equipment by choosing from among decisions $a = 1, \dots, h$, where $h \geq 2$. Decision h is to do nothing to the equipment. Decision 1 is to completely replace the equipment. Decisions $2, \dots, h-1$ correspond to various overhaul operations on the equipment. Assume that the set of allowable decisions $A(x)$ in state x is increasing in x , and $A(x')$ is a subset of $A(x')$ for $x' \leq x$. For instance, the firm may require that the equipment be either

overhauled or replaced in very low states, but that any decision is feasible in higher states. The replacement and overhaul operations are thorough enough that the distribution function $Q(w|x, a)$ of the state in the next period does not depend on the present state x if the firm makes a decision a with $a \leq h-1$. If the firm makes decision h and does nothing to the equipment, then a higher present state x makes it more likely that there is a higher state in the next period. Therefore, the distribution function $Q(w|x, a)$ of the state in the next period is stochastically increasing in the present state x . The firm receives the return $\rho(x, a)$ for making decision a in state x , and $\rho(x, a)$ is decreasing in the state x . Assume that if $x' \leq x''$, then $\rho(x', a) - \rho(x'', a)$ is increasing in the decision a on $A(x')$. According to Lemma 6 (Lemma 3.9.4. from [8], p. 164) the optimal control decisions increase with the state of the system.

A series of examples can be found in Chapter 3 in [8], p. 167; Chapter 8 in [1], p. 387; Chapter 4, [2], p. 108.

Finite Horizon Case

Definition 15. Let $K \subseteq \mathbb{R}^q$ and $S \subseteq \mathbb{R}^n$, and let $\int_K d\tilde{Q}_y(z)$ be the probability measure of K with respect to the distribution function $\tilde{Q}_y(z)$ on $\mathbb{R}^q$. $\tilde{Q}_y(z)$ is said to be stochastically supermodular in y on S if $\int_K d\tilde{Q}_y(z)$ is supermodular in y on S for each increasing subset K in $\mathbb{R}^q$.

Theorem 3 [Theorem 3.9.2. from [8], p. 165]. *Consider $\mathcal{M}$, a discrete-time nonstationary Markov decision process with finite horizon T . If we have for any $t \in \{0, 1, \dots, T-1\}$*

Condition 1. $A_t(x_t)$ finite and $\rho_t(\cdot, a_t), \rho_t(\cdot) : X(t) \rightarrow \mathbb{R}$ bounded

Condition 2. $S_t := \{(x_t, a_t) | (x_t, a_t) \in X(t) \times A_t(x_t)\}$ is a sublattice of the vector-lattice $\mathbb{R}^n = \mathbb{R}^q \times \mathbb{R}^m$

Condition 3. $A_t(x_t) \subset A_t(\tilde{x}_t)$ for all states $x_t \leq_{\mathbb{R}^q} \tilde{x}_t \in X(t) \subset \mathbb{R}^q$

Condition 4. $\rho_t(\cdot, a_t), \rho_T(\cdot) : X(t) \rightarrow \mathbb{R}$ are nondecreasing in x_t , for any $(x_t, a_t) \in X(t) \times A_t(x_t)$

Condition 5. $\rho_t(\cdot, \cdot) : X(t) \rightarrow \mathbb{R}$ are supermodular in $(x_t, a_t) \in S_t$

Condition 6. the distribution function for the state w in the period $t + 1$ given the state x_t and the action a , $Q_t(w|x_t, a_t)$, is stochastically increasing in x_t , for any $(x_t, a_t) \in X(t) \times A_t(x_t)$, and is stochastically supermodular in $(x_t, a_t) \in S_t$.

Then for any $t \in \{0, 1, \dots, T - 1\}$,

1. the function

$$w_t(x_t, a_t) = \rho_t(x_t, a_t) + \lambda \times \int f_{t+1}(z) dQ_t(z|x_t, a_t) \quad (4)$$

is supermodular in $(x_t, a_t) \in S_t$

2. $f_t(x_t) = \sup_{a_t \in A_t(x_t)} \{\rho_t(x_t, a_t) + \lambda \int f_{t+1}(z) dQ_t(z|x_t, a_t)\}$ is supermodular in $x_t \in X(t)$

3. the set of optimal decisions $\arg \max_{a_t \in A_t(x_t)} \{\rho_t(x_t, a_t) + \lambda \int f_{t+1}(z) dQ_t(z|x_t, a_t)\}$ is nondecreasing in the state $x_t \in X(t)$, and

4. there is a greatest (least) optimal decision for each state x_t and this greatest (least) optimal decision is increasing in $x_t \in X(t)$ (i.e., there exists at least one monotonic nondecreasing optimal policy).

Condition 1 can be reduced to X and A to be finite, or generalized [7] by conditions leading to the existence of an optimal action at each step such as compactness with smoothness conditions on $w_t(\cdot, \cdot)$.

In the proof of Theorem 3, f_t is supermodular as a sum of supermodular functions ($\rho_t(x_t, a_t)$ and $\int f_{t+1}(z) dQ_t(z|x_t, a_t)$). In applications, $\int f_{t+1}(z) dQ_t(z|x_t, a_t)$ nondecreasing in x means that a control has more of an impact when a state is “greater,” “at a higher level” (in the order of the state space) than when it is “at a lower level.”

The proofs of Theorem 3 also hold for the case in which $X(t)$ is only a sup-lattice, while

$A_t(x_t)$ is a lattice for any $x_t \in X(t)$. The other theorems for the finite horizon case are consequences of Theorem 3 stated in forms more convenient to be used.

Corollary 1 [[21], generalization of Lemma 4.7.2 from [2], p. 106]. Let $\{y_j\}_{j \in X}$, $\{\tilde{y}_j\}_{j \in X}$, $\{v_i\}_{i \in X}$ be real-valued nonnegative numbers indexed after $X \subset \mathbb{R}^q$ countable. Suppose $\sum_{j \in K} y_j \geq \sum_{j \in K} \tilde{y}_j$ for any increasing subset $K \subseteq X$ and the sums $\sum_{j \in X} y_j$, $\sum_{j \in X} \tilde{y}_j$ are finite. If for any $i, j \in (X, \leq_{\mathbb{R}^q})$ such that $i \geq_{\mathbb{R}^q} j$ we have $v_i \geq v_j$ then $\sum_{j \in X} v_j y_j \geq \sum_{j \in X} v_j \tilde{y}_j$.

This corollary of Lemma 5 is essential in determining the extent of generality of the state space in the discrete state space model, as it will be seen in the following Theorem 4.

By summarizing the results of [7], Theorem 4.7.5 from [2], p. 108 and using a discrete version of Theorem 3 from [8], p. 165 we have the following result.

Theorem 4. Consider $\mathcal{M}$ a discrete-time nonstationary Markov decision process with finite horizon T , and finite state and action space subsets of the vector-lattices $\mathbb{N}^q \times \mathbb{N}^m$. For any $t \in \{0, 1, \dots, T - 1\}$:

1. (a) $\rho_t(\cdot, \cdot)$ is supermodular/superadditive in $(x_t, a_t) \in X(t) \times A_t(x_t)$
 (b) $\rho_t(\cdot, a_t) : X(t) \rightarrow \mathbb{R}$ is nondecreasing
 (c) $\rho_T(\cdot) : X(T) \rightarrow \mathbb{R}$ is nondecreasing
2. (a) $A_t(x_t) \subset A_t(\tilde{x}_t)$ for any $x_t \leq \tilde{x}_t \in X(t) \subset \mathbb{N}^q$
 (b) $S_t := X(t) \times A_t(x_t)$ is a lattice with respect to the componentwise partial order on the product space $\mathbb{N}^n = \mathbb{N}^q \times \mathbb{N}^m$
 and for any increasing subset $K \subseteq X(t + 1)$
3. $Q_t(\cdot, \cdot) := \sum_{x_{t+1} \in K} p_t(\cdot, \cdot, x_{t+1})$ is supermodular/superadditive in $(x_t, a_t) \in X(t) \times A_t(x_t)$
4. $Q_t(\cdot, a_t) := \sum_{x_{t+1} \in K} p_t(\cdot, a_t, x_{t+1})$ is nondecreasing in $x_t \in X(t)$, for any $a_t \in A_t(x_t)$.

Then there exists an optimal policy nondecreasing in state.

Proof. Given

$$u_t^*(x_t) = \max_{a_t \in A_t(x_t)} w_t(x_t, a_t), \quad (5)$$

$$u_T^*(x_T) = \rho_T(x_T).$$

If $w_t(\cdot, \cdot) : X(t) \times A_t(x_t)$ is supermodular and the max is attained, Theorem 2 holds and

$$a_{x_t}^* := \max \arg \max_{a_{x_t} \in A_t(x_t)} w_t(x_t, a_{x_t}).$$

Let $a_t \leq_{\mathbb{N}^q} \tilde{a}_t \in \{A_t(x_t) \times A_t(\tilde{x}_t)\} \cup \{A_t(\tilde{x}_t) \times A_t(x_t)\}$ and $K \subseteq X(t+1)$ an increasing subset. To prove by induction in t that

$$\sum_{x_{t+1} \in X(t+1)} p_t(x_t, a_t, x_{t+1}) u_{t+1}^*(x_{t+1})$$

is supermodular in $(x_t, a_t) \in X(t) \times A_t(x_t)$ for any t we use that for any t , $Q_t(\cdot, a_t)$ is nondecreasing, S_t is a sublattice, the action family is expanding, as well as Corollary 1 with

- $x_t^- \leq x_t^+ \in X(t)$
- $a_t^- \leq a_t^+$, where $a_t^- \in A_t(x_t^-)$ and $a_t^+ \in A_t(x_t^+)$
- $y_j = [p_t(x_t^+, a_t^+, j) + p_t(x_t^-, a_t^-, j)]$, where $j \in X(t+1)$
- $\tilde{y}_j = [p_t(x_t^-, a_t^+, j) + p_t(x_t^+, a_t^-, j)]$, where $j \in X(t+1)$
- $v_j = u_{t+1}^*(j)$.

Checking Theorem 4's hypotheses for each increasing set is not an easy task. In [31] for a production control problem on for vector-lattices $\mathbb{N}^q$, a useful tool was the decomposition of any increasing set into elementary increasing subsets of the type

$$K_s = \{x \in X(t) \subseteq \mathbb{N}^q \mid x \geq_{\mathbb{N}^q} s\},$$

and the fact that any increasing subset of $X(t) \subseteq \mathbb{N}^q$ can be written as $\bigcup_{j=1}^r K_{s_j}$, where $s_1, \dots, s_r \in \mathbb{N}^q$.

Also Theorem 4's hypotheses are greatly simplified if $A_t(x_t) = A$ constant.

Corollary 2 [Theorem 4.7.4 from [17], p. 107]. Suppose for $X = \mathbb{N}$, $A(x) = A$, $t = 1, \dots, T-1$ that

1. $\rho_t(\cdot, a) : \mathbb{N} \rightarrow \mathbb{R}$ is nondecreasing for all $a \in A$
2. $p_t(\cdot, a, x_{t+1})$ is nondecreasing in $x_t \in \mathbb{N}$, for any $x_{t+1} \in \mathbb{N}$ and $a \in A$
3. $\rho_t(\cdot, \cdot)$ is supermodular(submodular) in $(x_t, a_t) \in \mathbb{N} \times A$
4. $p_t(\cdot, \cdot, x_{t+1})$ is supermodular(submodular) in $(x_t, a) \in \mathbb{N} \times A$ for all $x_{t+1} \in \mathbb{N}$
5. $\rho_T(\cdot) : \mathbb{N} \rightarrow \mathbb{R}$ is nondecreasing.

Then, there exist optimal decision rules $d_t^*(x)$, which are nondecreasing (nonincreasing) in x for $t = 1, \dots, T-1$.

The conditions for minimization problems from the Corollary 2 are a particular case of the general form from Theorem 8-16 from [1], p. 427.

Dragut [21] shows the existence of weakly monotonic optimal policies under less restrictive requirements than the ones from [7,8,17].

Proposition 1 [21]. Consider a discrete-time nonstationary Markov decision process with finite horizon T , and finite state and action spaces $\mathbb{N}^q \times \mathbb{N}^m$. If for any $t \in \{0, 1, \dots, T-1\}$ Conditions 1, 3, 4 of Theorem 4 hold and

1. $X(t)$, $A_t(x_t)$, for any $x_t \in X(t)$ are bounded subsets without holes of the infinite vector-lattice $\mathbb{N}^q \times \mathbb{N}^m$
2. $A_t(x_t) \subset A_t(\tilde{x}_t)$ for any $x_t \leq_{\mathbb{N}^q} \tilde{x}_t \in X(t)$, and $A_t(x_t) = A_t(\tilde{x}_t)$ for any $x_t, \tilde{x}_t \in X(t)$ not comparable (i.e., the family $\{A_t(x_t) \mid x_t \in X(t)\}$ is expanding)
3. for any $x_t \leq_{\mathbb{N}^q} \tilde{x}_t \in X(t)$, and $a \leq_{\mathbb{N}^m} \tilde{a} \in A_t(x_t) \times A_t(\tilde{x}_t)$ or $A_t(\tilde{x}_t) \times A_t(x_t)$ we have that $a \in A_t(x_t)$ and $\tilde{a} \in A_t(\tilde{x}_t)$ (i.e. the family is ascending) and if for any increasing subset $K \subseteq X(t+1)$

4. if $(\exists)x_t \neq \tilde{x}_t \in X(t)$ such that $A_t(x_t) \neq A_t(\tilde{x}_t)$ then $\sum_{x_{t+1} \in K} p_t(x, a_t, x_{t+1})$ is non-decreasing in $a_t \in A_t(x)$, for any $x \in X(t)$,

then there exist optimal decision policies, which are weakly monotonic nondecreasing in the state, for any $t \in \{0, 1, \dots, T-1\}$.

Equivalency between submodularity and weak submodularity on $X = \mathbb{R}^2$ is discussed in Theorem 8-4 from [1], p. 378.

Backward Induction Algorithms. The basis of this backward induction algorithm is the intuitive argument called *Principle of Bellman Optimality*: “An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.” The ideas behind backwards induction are as follows.

- Envision being in the last time period for all the possible states and decide the best action for those states. This yields an optimal value (max value for a maximization problem) for that state in that period.

$$\forall x_T \in X(T), \quad u_T^*(x_T) = \rho_T(x_T).$$

- Next envision being in the next-to-last period for all the possible states and decide the best action for those states (an elements of the $\arg \max$), given you now know the optimal values of being in various states at the next time period. This is done solving the optimality equation (2) at each stage t .
- Continue this process until you reach the initial time $t_0 = 0$.

Since the optimal policy must give optimal actions for each state, in the backward induction algorithm the optimal policy chosen is $\pi = \{d_t\}_{t \in \mathbb{N}}$, where $d_t = a_t^* \in \arg \max_{a_t \in A_t(x_t)} w_t(x_t, a_t)$.

From Section 4.7.6 in [2], p. 111, a monotonic backwards induction algorithm can only

be used for very particular nonstationary MDPs with finite X and with $A(x) = A$ for all $x \in X$. The monotonic backwards algorithm reduces the complexity of finding an optimal policy. It considers only nondecreasing control actions instead of the whole $A(x)$. Thus, the algorithm looks for candidate actions for the $\arg \max$ for a given state x only in the superior cones of the elements of the $\arg \max$ of all states $\tilde{x}$, which are smaller than x . A series of examples with different action spaces can also be found in Chapter 8 in [1], p. 428.

A more general algorithm can be derived for multidimensional state and action spaces but is not computationally feasible. Even very small lattices cannot be entirely handled in the main computer memory (with all the couples state–action subsets). Moreover, in many applications the state and action space are merely bounded subsets without holes in a countable lattice. If we strengthen the assumptions and we require the action space to be a lattice instead of partially bounded subset of $\mathbb{N}^m$, for all these unordered actions, there will exist a greater action (their maximum) in the vector order. In real life, however, such “max” actions imply a large increase of the state/action space, possibly canceling the computational gains brought by monotonicity. Avoiding this loss, requirements from Lemma 4 lead to weakly monotonic nondecreasing policies [21]: $X(t)$ and A_t are covered by disjoint antichains using Lemma 1; for each segment of lattice explored by the algorithm only its bottom and top are kept, and the search is “ordered” (antichain sweep between top and bottom—Fig. 1).

Infinite Horizon Case

For an infinite horizon problem ($T = \infty$), a stationary model (i.e., a model in which the parameters do not change over time) is a standard assumption in the literature. Following this assumption, we drop the time index t for the infinite horizon models presented in the rest of this article.

We consider $\{X, A, (A(x), x \in X), Q, \rho\}$ as a discrete-time infinite horizon stationary Markov control model with immediate rewards, where X and A are Borel spaces, and $Q(B|x, a)$ a stochastic kernel on

X . Consider $S := \{(x, a) | (x, a) \in X \times A(x), A(x) \text{ is a Borel subset}\}$ and $\rho : S \rightarrow \mathbb{R}$ a measurable function. Then $Q(\cdot | x, a)$ is a probability measure on X , for every $(x, a) \in S$, and $Q(B | \cdot, \cdot)$ is a measurable function on S , for every Borel set B on X .

A policy π and an initial state $x = x_0$ determine the Markov control process.

To grasp the mechanism behind the derivation of several types of monotonicity conditions in the infinite horizon case we present the interesting open research formulation made by [11] when presenting the result of [9].

Theorem 5 [9,11]. *Assume X, A are posets. α the discount factor then f_t is weakly increasing if for an arbitrary t the following hold.*

1. S is “monotonically complete” in the sense that $x \leq x'$, $a \leq a'$ and $(x, a), (x', a') \in S$ imply that (x, a) and (x', a') belong to S (i.e. $a \in A(x)$ and $a' \in A(x')$)
- 2.

$$w_t(x, a) := \rho(x, a) + \lambda \int f_{t+1}(z) dQ(z | x, a) \quad (6)$$

is finite and has increasing differences

3. there is a maximizer f_t at stage t such that $f_t(x)$ is weakly minimal in $D_t^*(x)$, $x \in X$, where $D_t^*(x)$ is the set of all decisions in $A(x)$ maximizing the Bellman optimality equation at stage t .

Then f_t is “weakly” increasing.

By considering the order “ $\geq$ ” instead of the order “ $\leq$ ” on X and A , one obtains the criteria for f_t to be decreasing (increasing). Different criteria to fulfill the requirements of “monotonically complete” led to several variants of the Theorem 5. Surely, for applications, new less restrictive criteria can still be developed starting from this formulation. Another source of results was Table 1 in [6], p. 312, which gives ways of constructing a supermodular/submodular functions.

Discounted Reward Criterion. In the case of the expected total discounted reward we distinguish among results with bounded and unbounded rewards.

In applications with evolving systems (queueing control, production) there is rarely a preset bound to the system state: the system “grows” and/or “shrinks” and the rewards/costs follow in a nondecreasing way—prior costs/rewards bounds are restrictive. Thus, Section 6.10 in [2], p. 232 sets relative bounds for the rewards growth with respect to the system state and limits the probability of reaching distant states.

Assumption 1 [Assumptions 6.10.1, 6.10.2 from Section 6.10 in [2], p. 232]. Suppose $\varpi : X \rightarrow \mathbb{R}_+$ satisfies $\inf_{x \in X} \varpi(x) > 0$. Also assume the following.

1. There exists a constant $\mu < \infty$ such that $\sup_{a \in A(x)} |\rho(x, a)| \leq \mu \varpi(x)$, for $x \in X$.
2. There exists a constant $0 \leq \kappa < \infty$, and for each $0 \leq \lambda < 1$, there exists an $0 \leq \beta < 1$ and an integer J such that for all $\pi = (d_1, \dots, d_J)$ where $d_k \in D^{\text{MD}}$ the set of deterministic Markovian decision rules, $1 \leq k \leq J$ hold
 - (a)

$$E^\pi \{\varpi(X_{t+1}) | X_t = s, d_t(X_t) = a\} \leq \kappa \varpi(x)$$

for all $a \in A(x)$ and $x \in X$.

(b)

$$E^\pi \{\varpi(X_{t+1}) | X_t = x\} \leq \beta \lambda^{-1} \varpi(x)$$

for $x \in X, t = 1, 2, \dots$,

These assumptions ensure the convergence of value iteration without a prior bound on rewards. The finite horizon results from Corollary 2 can be extended in the more general framework of obtaining structured optimal stationary policies from Section 6.11 in [2], p. 255.

Corollary 3 [Theorem 6.11.6 from [17], p. 258]. Suppose for $X = \mathbb{N}$ and $A(x) = A$ that Assumption 1 that

1. $\rho(\cdot, a) : \mathbb{N} \rightarrow \mathbb{R}$ is nondecreasing for all $a \in A$
2. $Q(\cdot, \cdot) := \sum_{y \geq k} p(\cdot, \cdot, y)$ is supermodular/superadditive in $(x, a) \in \mathbb{N} \times A$ for all $k \in \mathbb{N}$
3. $Q(\cdot, a) := \sum_{y \geq k} p(\cdot, a, y)$ is nondecreasing in $x \in \mathbb{N}$, for any $a \in A$ for all $k \in \mathbb{N}$
4. $\rho(\cdot, \cdot)$ is supermodular/submodular in $(x, a) \in \mathbb{N} \times A$.

Then, there exists an optimal stationary policy $(d^*)^\infty$ with the property that $d^*(x)$ is nondecreasing (nonincreasing) in x .

This holds since the pointwise limit of any sequence of nondecreasing functions is nondecreasing. To ensure the existence of a nondecreasing decision, the hypothesis is stated using the elementary increasing sets on $\mathbb{N}$.

In the monotone value iteration algorithm, the maximization can be carried out only over structured action sets (Section 6.11 in [2], p. 259).

For state and action spaces intervals on $\mathbb{R}$, [32] gives alternative sets of sufficient conditions for $w_t(x, a)$ in Equation (6) to have increasing/decreasing differences. Conditions for where the states have a linear dependency (Conditions 1, 2) are given under the following common assumptions:

Assumption 2 [Assumptions 4.2 from [32]; and 4.2.1 and 4.2.2 from [33], p. 46].

1. X and A are intervals on $\mathbb{R}$.
2. $(1 - \lambda)a + \lambda a' \in A(1 - \lambda)x + \lambda x'$, for all $x, x' \in X$, $a \in A(x)$, $a' \in A(x')$, $\lambda \in [0, 1]$, $A(y) \subset A(x)$, for $x \leq y$ in X , and $A(x)$ is convex for all $x \in X$.
3. ρ is convex on S .
4. The one-stage cost $\rho : S \rightarrow \mathbb{R}$ is nonnegative, lower semicontinuous, and inf-compact on S .
5. The transition law Q is strongly continuous.
6. There is a policy π such that its expected total discounted cost $V_\alpha(\pi, x) < +\infty$ for all $x \in X$.

Condition 1.

1. Q is given by $x_{t+1} = \gamma x_t + \delta a_t + \xi_t$, $t = 0, 1, \dots$, $\gamma, \delta > 0$, and $\{\xi_t\}$ is a sequence of i.i.d. r.v., which take values in $Z \subset \mathbb{R}$.
2. (Obviously, assuming that $\gamma x + \delta a + z \in X$, for all $x \in X$, $a \in A(x)$, and $z \in Z$.)
3. $x \rightarrow A(x)$ is descending.
4. ρ is supermodular on S .

Condition 2.

1. S is a lattice.
2. Consider Requirement 1 from Condition 1, but changing $\gamma, \delta > 0$ by $\gamma > 0$, $\delta < 0$
3. $x \rightarrow A(x)$ is ascending.
4. ρ is submodular on S .

Theorem 6. Suppose Assumption 2 holds. Then there is a decreasing stationary optimal policy under Condition 1 and an increasing stationary optimal policy under Condition 2.

Flores-Hernandez and Montes-deOca [32] also draw conditions for nonlinear models. Other results on monotonicity and convexity of the optimal value function for discounted MCPs are provided in Lemmas 6.1 and 6.2 from [34].

Relevant research has also been developed by assuming that the reward function is bounded over the domain of the state space. Some monotonicity results have the submodularity of the DP operator given directly [1, 6, 9, 35–39] and some in terms of the elements of the Markov control model [1, 7, 11, 22, 40]. One popular criterion for submodularity on $X = \mathbb{R}^2$ is that w_t is twice differentiable on a convex set and has a nonnegative second partial derivative (Corollary 8-1 from [1], p. 376). The proof of this criterion led to the aforementioned economic interpretation of submodularity.

For a general real poset state space the monotonicity conditions are attained by imposing the objective function to be lower/upper semicontinuous and the state space to be a compact set such that it can achieve its minimum/maximum. Thus in

general, lattice DP is stated in Corollary 8-4 from [1], p. 380 and particularized for $X = \mathbb{R}^2$ applications in Theorem 8-5 p.381, Corollary 8-5a, Corollary 8-5b. The result on $X = \mathbb{R}^2$ is also given in a Markov control setting in Theorem 8-16 p.427.

For countable poset state space, the theorem in [7] states the existence conditions for structured optimal decision rules, with respect to the state of the system. It considers discrete MDPs with $S_t := \{(x_t, a_t) | (x_t, a_t) \in X(t) \times A_t(x_t)\}$ sublattice of an arbitrary lattice, and with summarized utility functions.

For an infinite horizon stationary discounted $\mathcal{M}$ model, Theorem 3 holds (Section 39 from [8], p. 166).

In [41,42] alternative sets of conditions are derived for achieving the existence of monotonically nondecreasing optimal policies for the discounted stationary Markov control process with state space subset of $\mathbb{Z}^N$, the admissible actions set $A(x)$ finite for any $x \in X$ and with the immediate nonnegative rewards bounded on $S := X \times A(x)$. Theorem 4 holds provided that an optimal pure stationary policy exists. Numerical consequences for the infinite-stage model are investigated in [43,44].

Average Expected Reward Criterion. For applications, structural results for the average reward models were obtained by using the limit of discounted models a long time ago [45]. Derman [46], p. 121 and Tijms [47], p. 221 provide examples of structured policy iteration algorithms.

Under the vanishing discount approach for countable-state models, results similar to the discounted infinite horizon ones from Corollary 3 are established (Section 8.11 in [2], p.225) in the general framework of obtaining structured optimal stationary policies.

Assumption 3 [Assumptions 8.10.1, 8.10.2, 8.10.3, 8.10.4 from [2], p. 415].

1. For each $x \in X \subset \mathbb{N}$, $-\infty < \rho(x, a) \leq R < \infty$.
2. For each $x \in X$ and $0 \leq \lambda < 1$, the solution of equation (5) $u_\lambda^*(x) > -\infty$.

3. There exists a $K < \infty$ such that, for each $x \in X$, $u_\lambda^*(x) - u_\lambda^*(0) \leq K$ for $0 \leq \lambda < 1$.
4. There exists a nonnegative function $M(x)$ such that
 - (a) $M(x) < \infty$
 - (b) for each $x \in X$, $u_\lambda^*(x) - u_\lambda^*(0) \geq -M(x)$ for all λ , $0 \leq \lambda < 1$ and
 - (c) there exists an $a_0 \in A_0$ for which $\sum_{y \in X} p(0, a_0, y)M(y) < \infty$.

Corollary 3 [Theorem 8.11.3 from [17], p. 426]. Suppose that $X = \mathbb{N}$ and $A(x) = A$ and Assumption 2 and the ones in Corollary 3 hold.

Then there exists a $\liminf$ average optimal stationary policy $(d^*)^\infty$ with the property that $d^*(s)$ is nondecreasing (nonincreasing) in s . Further, when X is finite, $(d^*)^\infty$ is average optimal.

A monotone policy iteration algorithm is presented for a unichain model.

For state and action spaces intervals on $\mathbb{R}$, in [32] there are derived increasing/decreasing stationary optimal policies under similar assumptions with the discounted case. Noncountable Markov control processes examples are discussed there as well as in Example 5.4.2 from [33].

Optimal Monotone Policies–Based Algorithms. In the absence of a uniqueness assumption on optimal policies, a series of approximating finite MDP problems approximate the underlying infinite MDP problem's optimal value. In [48,49] monotonicity of optimal policies is exploited to establish the existence and discovery of solution and forecast horizons in a class of nonhomogeneous MDPs. Garcia and Smith [48] used a “forecast index” such that the first-period optimal decision is monotonically nondecreasing in that index. Cheevaprawatdomrong *et al.* [49] do not require the uniqueness of an infinite horizon optimal first policy. Their assumption is called *well-posedness*, that is, a first-period optimal decision can be determined by the data associated with a finite number

of periods of problem data. The property exploited was monotonicity of the first decision with respect to problem horizons, which generalizes [50].

Other Markovian Models

Consider a POMDP model as in ***Partially Observable MDPs (POMDPs): Introduction and Examples***. A finite action/state space, POMDP model can be analyzed by transforming it into an equivalent continuous-state MDP in which the system state is a probability distribution on the unobserved states in the POMDP, and transition probabilities are derived through Bayes' rule (see ***Reduction of a POMDP to an MDP***). Therefore, standard solution techniques used for solving MDPs can also be used for solving POMDPs. Smallwood and Sondik [51] present conditions for general POMDPs under which, if there are only a finite number of control intervals remaining, the optimal payoff function is piecewise-linear and convex. Sondik [52] extends these results to the infinite horizon discounted case. In this framework for a discrete-time finite POMDP, Lovejoy [53] uses likelihood ratio ordering to provide sufficient conditions for the optimal value function to be a monotone.

For POMDPs with finite or countably infinite (core) state and observation spaces and finite action sets, see [54]. For monotonicity results on general state, action, and observation spaces we refer to [55].

In optimal inspection [56] and replacement [40], the stochastic ordering was used to derive monotonicity results on subsets of the action space. A general set of conditions was derived in [57] for countable-state problems and a survey followed in [58].

The “stochastically increasing” ordering led to more restrictive conditions due to the first-order stochastic dominance interaction with the conditioning as pointed out by [54] when investigating POMDPs with three or more states.

The monotonicity was also used for the value function approach to approximate the optimal value function with a function defined over the same information space.

Monotonic structure results are derived in the constrained MDPs for the flow control in communication networks. Extensive reviews can be found in Section 16.6 in [59], p. 503 and Chapter 5 in [60], p. 45.

Other structural results concerning randomized monotone policies in infinite horizon average-cost constrained MDP can be found in [61,62].

COMPARABLE STATISTICS FOR THE OPTIMAL MONOTONIC NONDECREASING POLICIES

DP problems provide optimal policies often too complicated to be used for deriving insights. Intuitively one might expect that the monotonicity of the decision rules would imply a stable structure of the optimal paths (i.e., an increase in a exogenous parameter θ will lead to a uniform change of the optimal path). This might be true in the unidimensional stationary case [63]. In [64] a two-dimensional example of a chaotic optimal path for a monotonic decision rule is given, as well as an analysis of connections between monotonic policies and the optimal path when $A_t(x_t)$ are sublattices of $\mathbb{R}^m$ for any $x_t \in X(t)$. The authors consider a general dynamic decision problem (DDP), where in each period, the set of allowable actions may depend on the action from the previous period, as well as of the current state, and a set of exogenous parameters $\Theta := \Theta_1 \times \dots \times \Theta_l$, where $\Theta_i \subseteq \mathbb{R}$ is locally compact. For the DDP considered it is described by: an action space $A = A_1 \times \dots \times A_n$, $A_i \subseteq \mathbb{R}$, and A_i locally compact, such that A is a vector-lattice, a finite set of random stationary Markovian processes $x_i^t \in X_i$, having a positive persistence of uncertainty, where $X = X_1 \times \dots \times X_m$, $X_i \subseteq \mathbb{R}$, and X_i locally compact, and the payoff per period $F(a^t, a^{t-1}, x^t; \theta) + \sum_i \kappa_i(a_i^t)$, where both $F(a^t, a^{t-1}, x^t; \theta)$, and $\sum_i \kappa_i(a_i^t)$ are upper semicontinuous. The assumptions considered were:

1. the value function exists and is well defined under total expected reward criterion.

2. the graph $\Gamma := \{(a, a', x; \theta) | a \in A(a', x; \theta)\}$ is a sublattice of $A \times A \times X \times \Theta$ (in the product order), where $A(a', x; \theta)$ is the set of allowable actions in state x .
3. $A(a', x; \theta)$ is a complete sublattice of A .
4. $F(a, a', x; \theta)$ is supermodular in $(a, a') \in \Gamma(x; \theta) := \{(a, a') | a \in A(a', x; \theta)\}$ and has nondecreasing differences in $((a, a'), (x; \theta))$ on $A(a', x; \theta)$ (i.e., full complementarities).

Proposition 2 [64]. *Consider a dynamic decision problem with a monotone decision rule. Then for any initial conditions s^0, x^0 and any two parameter choices $\theta^+ \geq \theta^-$, for all $t > 0$, $a^t(\theta^+) \geq a^t(\theta^-)$ along any sample path, where in every period the largest optimal action is always chosen.*

As a consequence, we have a robustness result that can also be derived independently as a direct consequence of Theorem 2.

Corollary 4. *Let A be a lattice, $\Theta \subset \mathbb{R}^p$ a sublattice, and X a partially ordered set with $A_{x,\theta} \subseteq A$ for any $(x, \theta) \in X \times \Theta$. If we have*

1. *for each $(x, \theta) \in X \times \Theta$ there exists $\max_{a \in A} g(x, \theta, a)$*
2. *$A_{x,\theta}$ is increasing in $(x, \theta) \in X \times \Theta$*
3. *$g(x, \theta, \cdot) : A \rightarrow \mathbb{R}$ is supermodular in $a \in A$ for each $(x, \theta) \in X \times \Theta$, and has increasing differences in $((x, \theta, \cdot) \in X \times \Theta \times A)$,*

then for any $x^+ \geq_X x^- \in X$, $\theta^- \leq_{\mathbb{R}^p} \theta^+ \in \Theta$, we have that

$$\begin{aligned} & \max_{a \in A} \arg \max_{a \in A} g(x^-, \theta^-, a) \\ & \leq \max_{a \in A} \arg \max_{a \in A} g(x^+, \theta^+, a). \end{aligned}$$

Similar results can be obtained for weakly nondecreasing monotonic policies with or without separable objectives [21].

CONTINUOUS-TIME MODELS

For *semi-Markov decision processes* (SMDPs) we refer to Chapter 11 in [2], p. 530. In the case of discounted criterion, the discounted semi-Markov problem is transformed in a discrete-time model with a discount given by a decision rule–dependent factor. If Assumption 3 holds in the associated discrete-time model, then the results concerning the existence of solutions of the optimality equation and optimal policies hold as well.

Assumption 4. [Assumption 11.1.1 from [2], p. 532]. Let $F(t|x, a)$ be the probability that the next decision epoch occurs within t time units of the current decision epoch; given the chosen action a from $A(x)$ in state x at the current decision epoch, there exist $\varepsilon > 0$ and $\delta > 0$ such that

$$F(\delta|x, a) \leq 1 - \varepsilon$$

for all $x \in X$ and $a \in A(x)$.

For bounded rewards and finite $A(x)$ (or under the alternative conditions), Theorem 11.3.2 from [2], p.545 states the existence of an optimal stationary deterministic policy and the convergence of the value iteration algorithm.

For unbounded rewards, Theorem 11.3.3 from [2], p. 547 states the conditions for the convergence of the policy (modified) iteration algorithm: as a consequence of its convergence, the discrete case monotonicity results still hold.

For the average reward criterion in Section 11.4.3 from [2], p. 556, transform the model to an equivalent discrete-time model using the transformation. For the finite state case and $A(x)$ finite (or under the alternative conditions) and a unichain transition probability matrix for every stationary policy Theorem 11.4.6, p. 557 ensures the use of the discrete case results.

For general assumptions see [22,27].

For a general continuous-time Markov Decision Processes (CTMDP) the use of uniformization for analyzing Markov processes was formalized by [65] in the context of countable-state continuous-time models

with uniformly bounded transition rate. See also Section 11.5 in [2], p. 561. For both discounted and average reward criteria the discrete case monotonicity results hold in the equivalent discrete-time MDP.

The research for the existence of a monotonic optimal policy in CTMDP was related to controlled queueing systems and their threshold policies. Seminal papers were [66] for multimodular functions and [67] for switching. For the relation between multimodularity and submodularity we refer to Section 10.7 in [68], p. 218.

Going beyond problem specific proofs two general techniques are used. A DP one [69–71] generalized by discrete event systems DP in [5, 68, 72–74].

The value function is a composition of event (as arrivals controlled/fork arrivals, departure, tandem departures) operators. Since events occur only at transition times, the classical uniformization operator is replaced by a concatenation of such operators. The submodularity/increasingness properties are studied per operator. After the “uniformization” takes place, the embedded MDP is studied. Fictitious transitions might be added in some states. In event-based DP, establishing the structure of an optimal policy can then be performed by verifying that the different operators constituting the problem satisfy certain properties. This decomposition of the problem is extremely useful, since the properties of commonly used operators in queueing control problems can be investigated individually for once and indexed as in [5]. Thus, if a queueing control problem is composed of known operators, establishing the structure of the optimal policy is usually trivial by checking the already investigated operators. The event-based DP also studies the propagation of two more types of second-order properties related to convexity: multimodularity in [66] and directional convexity in [75, 76] and later in [25].

A second technique is the sample path one as in [77–81]. Compared to the technique based on propagating submodularity/supermodularity through DP optimality equations in an MDP setting, sample path analysis can solve only a subset of problems,

but it provides more insight and it requires a set of assumptions less restrictive than the Markovian ones. A review of different ways of comparing sample paths based on the ideas of vector majorization and set dominance can be found in [81]. They group the proof techniques into three general classes: forward induction, backward induction, and interchange arguments. They focus on deterministic policies, but using [82] proofs can be extended to randomized policies. Comparisons of the expectations of functions of one or more state variables are allowed only after the policies have been compared on a pathwise basis.

In order to apply the forward induction, one identifies a so-called hypothesized optimal policy and also derives the equations that capture the time behavior of the system under any policy. The proof then consists of a forward induction argument over times of all distinct events, establishing an ordering between the hypothesized optimal policy and the arbitrary policy. There might be more than one way to describe the evolution of the system considered, but as the authors point out not all of them make possible the comparisons between the optimal policy and an arbitrary policy. The technique was employed for the optimality of the μc rule for the multiclass $G/M/1$ queue and for reviewing the cases of the optimality of the *JSQ* (“join-the-shortest-queue”) rule in the control of routing to symmetric parallel queues.

As in forward induction, the backward induction compares the hypothesized optimal policy to an arbitrary policy. The proof requires more insight on the structural properties of the hypothesized optimal policy since in the induction step t , it is considered a policy that made the same decisions as the arbitrary one and then switches to the optimal one for the remaining decision stages. The technique was used for the optimality of the *Smallest Workload* rule for the multiclass $G/M/1$ queue with workload information.

The approach based on interchange arguments is generally the most popular and the most error prone. It is then essential to verify that the statistics of the input data have not been changed and that inadmissible control actions (see definition in Section 2 in [81]) are

Table 2. Structural Properties

$h(z)$	$g(x, y) =$	$g(x, y)$
Concave	$h(x + y)$	Jointly concave decreasing differences
Concave	$h(x - y)$	Jointly concave increasing differences
Convex	$h(x + y)$	Convex increasing differences
Convex	$h(x - y)$	Convex decreasing differences

not generated. This approach tries to show that the policy can be improved through the interchange of control decisions and/or the order of some events in the input sequence (typically, arrival times of customers, service times, routings). The comparison of policies is based on coupling [83], the same probability space [81], or a reduced new space followed by a proof of the optimality of the policy in the original model [84].

Among the papers that review optimal control on a sample path basis we refer also to [85] for scheduling problems and to [86] for communication networks. For a general overview see [87].

SUBMODULARITY AND CONVEXITY. GENERAL STRUCTURED OPTIMAL POLICIES

There are some qualitative analogies between submodular functions on lattices and convex functions on convex sets as emphasized by Table 1, giving ways of constructing submodular functions. Submodular functions are often considered as a discrete analog to convex functions [88].

Other structural properties relating the convexity/concavity with the monotone differences are presented in (Lemma 2.6.1 from [8], Section 2.6.2 Transformations, p. 49) Table 2. These were proven useful in the control of queues for obtaining a characterization of submodular types for the value functions (either direct [15], or indirect, in defining the operators in the event-based DP [5]).

Both submodularity and convexity are second-order properties in the sense that for twice differentiable functions on open

sets in $\mathbb{R}^n$ each property is equivalent to certain conditions on the matrix of second partial derivatives. The exact statement of Topkis's Theorem 1 holds for convex functions on convex sets, and this analogy was useful in finding certain properties of submodular functions. Among the closure (closed convex cone) properties, which are useful in propagating structural properties via DP there are

- the convex cone properties: expectation preserves convexity/concavity and monotonicity
- the single point properties: maximization preserves convexity and monotonicity as it does with the submodularity, while the maximum of jointly concave functions is concave.

In [23] the authors discuss in detail the convex cone properties and give a set of metatheorems that describe how properties of value functions are preserved and propagated through MDPs. Their main results say that the value functions satisfy property P among the convex cone ones closed under maximization or minimization if the reward functions satisfy property P and the transition probabilities satisfy a stochastic version of this property. For stationary finite horizon minimization MDP problems with real state and action space, monotone optimal policies can be characterized with convexity/concavity and submodularity, see Theorem 8.3 from Chapter 8 in [89], p. 127 as well as Theorem 3.10.2, Theorem 3.10.3 from Chapter 3 in [8], p. 172. For results in a more general context see [27].

In inventory management problems, the idea to defer orders until the inventory level was at a low enough level (s) so that the setup cost will be incurred when a large enough amount (at least $S - s$) is ordered had been appealing to researchers in the 1950s. However, its proof eluded them because the value function in the DP formulation of the problem was neither convex nor concave. Finally, [90] provided a proof by introducing a new class of functions called K -convex functions.

The easiest way of seeing it is that a K -convex function must lie below the line segment connecting $(y, h(y))$ and $(y', h(y') + K)$ on the interval $[y, y']$. Such a function can be discontinuous, but the jumps at the discontinuity point must necessarily be downwards and cannot be too large. Other seminal papers were [91,92]. This family of problems can be seen in the more general context of separable MDP as in Chapter 7 in [1], p. 307.

For general references on structured solutions for MDPs see the overall unified perspectives of [11]; Section 7.1 Structured Policies in [93], p. 147; Section 6.11, p. 255 and Section 8.11, p. 425 in [2]; Section 5.4 in [89], p. 87 (finite horizon); [94] (infinite).

For POMDPs with finite or countably infinite (core) state and observation spaces and finite action set see [95]. For countable stage decision processes see [96,97].

APPLICATIONS

This is not an extended overview, we just grouped some interesting monotonic policies according to the solution methodology. For one-dimensional problems, a monotone policy is often in the form of a control limit policy, while for two-dimensional problems, it is often in the form of a switching curve. On switching curves in the two-dimensional state space, the seminal paper is [66] discussing the optimal control of a Markov network with two service stations and linear cost. For switching curves in manufacturing we also refer to [70].

A general framework of obtaining monotone policies was the event DP (see the section titled “Continuous-Time Models”) established for the optimality of routing [80], admission control, service rate, general flow control policies that are monotone in the state, under different information structure. In [5] it was recently used to compare different systems differing in several operators, but for which the value function was the same.

The monotonicity in the case of a single queue has been studied in [9,38,50,98–102]. The monotonicity in the case of a network is treated in [67,71,80,103–105] (see also [73,74] for extensions) [106].

In corrective maintenance, a typical control limit policy is in [107] for an $M/G/1$ queueing system with an unreliable server. Classical monotonicity is derived in the corrective approach of [108] for parallel servers subject to random failure, or in the opportunistic maintenance approach of [109] for a k different types of components. For a review see [110–112].

In dynamic models, short-term information such as a varying deterioration of components or unexpected opportunities can be taken into account and decisions may change over the planning horizon. Thus, a specific type of monotonic optimal policy developed in maintenance is the *At-Most-Four-Region* (AM4R) policy introduced by [113] and further studied by [114] in the POMDP setting. A monotonic AM4R policy along an ordered set of knowledge states may change at most three times, and changes are following a pre-set sequence. It is supposed that the more deteriorated the system is, the more likely it is to deteriorate further and/or to fail. Also, if a knowledge state is stochastically less than another, then the system is “less deteriorated” in the “smaller” state, following the idea that no news is good news. The order considered was likelihood ratio ordering.

A more general type of policy called *component/marginally monotone* is found in [115,116]. Other maintenance papers with monotone optimal policies are [117–123].

For a monotonicity in binary and stochastic inventory models we refer to Chapter 8 in [89, p. 119].

In other application areas there exist direct monotonicity proofs using the general theory as in production and innovation [48,124], Chapter 5 in [48] pp. 188, [24,125–127] or staffing problems [120].

Consider an MDP problem having a monotone optimal policy in one or two dimensions, while for higher dimensions its optimal policies can only be found numerically. Then for higher dimensions, one might use heuristic methods leading to monotone policies. This is the case of a manufacturing application studied by [128,129]. For scheduling a single machine producing several different classes of items in a make-to-stock mode, the optimal policy is monotone for the case of

two products and backordering. For higher dimensions [130] derive heuristic index policies and hedging points (idleness policies). For the index policies, an index is computed for each class as a function of the inventory in that class. The class with the smallest index is produced, while if all indices are positive, the machine is idle. The concepts of monotone switching and monotone idling are used to describe the monotonic policies. This means that B_k , the set of states in which class k is preferred is bounded by an increasing switching surface and by a decreasing idling surface. For a review of such heuristics, see [131].

Acknowledgments

The author would like to thank Ad Ridder from Vrije Universiteit Amsterdam; Lisa Maillart, Jeffrey Kharoufeh from University of Pittsburgh; and the anonymous referees for their suggestions and insights, which improved this manuscript.

SUBGRADIENT OPTIMIZATION

YURI NESTEROV

Econometrics (CORE), Université
Catholique de Louvain (UCL),
Louvain-la-Neuve, Belgium

GENERAL NONSMOOTH OPTIMIZATION PROBLEM

General nonsmooth optimization problem has the following form:

$$\min_{x \in R^n} \{f_0(x) : f_i(x) \leq 0, i = 1, \dots, m\}, \quad (1)$$

where some of functional components $f_i(x)$ are nondifferentiable. The absence of differentiability creates serious theoretical difficulties on different levels (optimality conditions, definition, and computation of search directions, etc.).

Let us start from the definition of differential characteristics of nondifferentiable functions. Its most popular version was suggested by Clarke [1] (for alternative approaches, see Refs 2–4).

Definition 1. Let f be locally Lipschitz continuous at point $x \in R^n$. The Clarke *directional derivative* of f along $v \in R^n$ is defined as

$$\hat{f}(x, v) = \limsup_{\substack{x' \rightarrow x \\ t \rightarrow +0}} \frac{1}{t} [f(x' + tv) - f(x')]$$

The Clarke *subdifferential* of f at x is the set

$$\partial_C f(x) = \{g \in R^n : \langle g, v \rangle \leq \hat{f}(x, v) \forall v \in R^n\}.$$

Then, the Clarke *subgradient* of f at x is an arbitrary element from $\partial_C f(x)$.

If f is differentiable at x , then $\partial_C f(x)$ consists of a single element, the gradient $\nabla f(x)$.

Clarke subdifferential appears to be very convenient for theoretical analysis of nonsmooth optimization problems (see Ref. 4 for recent extensions and discussions). For example, it is possible to write down the first-order necessary optimality conditions for problem (1) in the following natural form:

$$\begin{aligned} g_0 + \sum_{i=1}^m \lambda_i^* g_i &= 0, \\ g_i &\in \partial_C f_i(x^*), \quad i = 0, \dots, m, \\ \lambda_i^* g_i(x^*) &= 0, \quad \lambda_i^* \geq 0, \quad i = 1, \dots, m. \end{aligned} \quad (2)$$

This is the *generalized Karush–Kuhn–Tucker condition*. If $m = 0$, this condition becomes

$$0 \in \partial_C f(x^*). \quad (3)$$

However, from the viewpoint of numerical methods, the situation is not so good. First of all, Clarke subdifferential is not supported by a proper calculus, which should allow to arrange the computation of its elements by a sequence of operations used for computing the function's value. Let us look at the following example.

Example 1. Define $f_1(x) = \max\{x, 0\}$, $f_2(x) = \min\{x, 0\}$. Then

$$\begin{aligned} \hat{f}_1(0, v) &= f_1(v), \quad \partial_C f_1(0) = [0, 1], \\ \hat{f}_2(0, v) &= f_2(v), \quad \partial_C f_2(0) = [0, 1]. \end{aligned}$$

However, $f(x) = f_1(x) + f_2(x) \equiv x$, and there is no simple way for getting the correct answer $\partial_C f(0) = \{1\}$ using some operations with the sets $\partial_C f_1(0)$ and $\partial_C f_2(0)$. At least the natural receipt $\partial_C f_1(0) + \partial_C f_2(0)$ does not work.

Fortunately, for the majority of nonsmooth optimization methods, at each test point we need to compute only a single element from Clarke subdifferential. This can be done by

the technique of *lexicographical differentiation* [5]. Define the directional derivative

$$f'(x, h) = \lim_{\alpha \rightarrow +0} \frac{1}{\alpha} [f(x + \alpha h) - f(x)].$$

Note that it transforms a function of x into a function of h . Let us introduce the corresponding linear operator

$$\phi = H_x[f] \Leftrightarrow \phi(h) = f'(x, h).$$

For defining a lexicographic gradient of function f at point x , we need to fix a basis $U = (u_1, \dots, u_n)$ in R^n . Then we can define the sequence of functions

$$\begin{aligned} f_{x,U}^{(0)} &= H_x[f], \\ f_{x,U}^{(k)} &= H_{u_k}[f_{x,U}^{(k-1)}], \quad k = 1, \dots, n. \end{aligned}$$

It can be proved that $f_{x,U}^{(n)}$ is a linear function. Its gradient is called the *lexicographic gradient* of function f at x along the basis U .

For lexicographic gradients we have a perfect Chain Rule. Hence, these gradients can be computed even by automatic differentiation. Lexicographic gradients are some special elements of Clarke subdifferential. At the same time, they satisfy all natural properties of the usual gradient.

The majority of nonsmooth optimization methods are justified by the proof of convergence to Clarke stationary points defined by Equation (3). Unfortunately, this result is much weaker than the similar statement for the smooth optimization problems. Indeed, consider the unconstrained minimization problem (1) with $m = 0$ and the following objective function:

$$\begin{aligned} f_0(x) &= \frac{1}{4} |1 - x^{(1)}| + \sum_{i=1}^{n-1} |1 + x^{(i+1)} - 2|x^{(i)}||, \\ x^* &= (1, \dots, 1). \end{aligned} \quad (4)$$

This is a unimodular function with no saddle points. For each point $x \neq x^*$ there exists a direction of strict linear decrease of the function value. Unfortunately, this function has exponentially many Clarke stationary points. For $n \geq 4$ and the starting point $x_0 =$

$(-1, 1, \dots, 1)$, this problem remains very challenging for the modern methods of general nonsmooth minimization.

Among the existing methods for approximating Clarke stationary points, we should mention the *bundle* methods [6,7], and the *gradient sampling* methods [8]. The former methods are trying to decrease the value of the objective function by updating a piecewise linear model constructed around the current prox-center (see Ref. 9 for detailed discussion). The model is dynamically improved by incorporating new elements computed at the minimizers of the current version of the model. If a significant decrease of the objective function is achieved, the prox-center is moved to a new location. This idea admits a full theoretical justification for convex case (we discuss it in the next section). In non-convex situation, the worst-case complexity guarantees for this approach are necessarily quite weak. Let us look at the following example.

Example 2. Let vector $c \in R^n$ have positive integer coefficients. Consider the function

$$\begin{aligned} \phi_c(x) &= \left(1 - \frac{1}{\sum_{i=1}^n c^{(i)}} \right) \max_{1 \leq i \leq n} |x^{(i)}| \\ &\quad - \min_{1 \leq i \leq n} |x^{(i)}| + |\langle c, x \rangle|. \end{aligned}$$

It appears that the problem of finding $x \in R^n$ with $\phi_c(x) < 0$, or proving that this is impossible, is NP-hard. Thus, for a bundle method started at $x = 0$, we can hardly hope that it can find a direction of strict decrease of ϕ_c . This direction corresponds to the integer solution of equation $\langle c, x \rangle = 0$ with entries ± 1 .

The gradient sampling methods select the test points randomly around the current center. For the majority of practical applications, the objective function at these points is differentiable with probability 1. Hence, the gradients at these points can be used for approximating the Clarke subdifferential at

the center. Unfortunately, the random scanning in a high-dimensional space is very expensive. Consider the following example.

Example 3. Let all coefficients of the vector $\sigma \in R^n$ be ± 1 . Consider the following function:

$$f_\sigma(x) = \max_{1 \leq i \leq n} |x^{(i)}| - 2 \max \left\{ 0, \min_{1 \leq i \leq n} \sigma^{(i)} x^{(i)} \right\}.$$

This function can be used in the *resisting oracle* fighting against the gradient sampling technique. As far as the number of calls of this oracle is smaller than $2^n - 1$, it can continue returning the differential characteristics of the first part of f_σ reallocating σ to be one of the missing sign patterns among all test points. Thus, in order to discover the full picture, we need at least 2^n calls. Note that along the direction σ function f_σ has linear decrease.

CONVEX PROBLEMS

Consider now the *convex* optimization problem:

$$\min_{x \in Q} f(x), \quad (5)$$

where $Q \subseteq R^n$ is a closed convex set, and function f is closed and convex on Q . Then, at each point $x \in Q$ there exists a subdifferential $\partial f(x)$:

$$f(y) \geq f(x) + \langle g_x, y - x \rangle, \quad \forall g_x \in \partial f(x), \quad \forall y \in Q. \quad (6)$$

Thus, the necessary and sufficient optimality condition at point $x^* \in Q$ can be written in the following form:

$$\exists g^* \in \partial f(x^*) : \langle g^*, x - x^* \rangle \geq 0 \quad \forall x \in Q.$$

The majority of practical methods for solving Equation (5) requires computation of a single *subgradient* $g_x \in \partial f(x)$ at each test point $x \in Q$. Since for nonsmooth functions

it is difficult to ensure a monotone decrease of the objective, the computational strategies of *subgradient methods* are based on the following inequality:

$$\langle g_x, x - x^* \rangle \geq 0, \quad x \in Q. \quad (7)$$

The earliest subgradient schemes employed the fact that by Equation (7) the *Euclidean distance* between the current test point and the optimal one can be decreased by an appropriate move along the direction of *antigradient* $-g_x$. The simplest *primal* subgradient method [10,11] looks as follows:

$$x_0 \in Q, \quad x_{k+1} = \pi_Q(x_k - h_k g_{x_k}), \quad k \geq 0, \quad (8)$$

where $\pi_Q(x)$ denotes the Euclidean projection of point x onto the set Q . The appropriate choice of the step sizes are as follows:

$$h_k = \frac{1}{\|g_{x_k}\|} \cdot \frac{R}{\sqrt{k+1}}, \quad h_k = \frac{f(x_k) - f(x^*)}{\|g_{x_k}\|^2},$$

where R is an estimate for $\|x_0 - x^*\|$. In both cases, it is possible to prove the following *rate of convergence*:

$$\min_{0 \leq i \leq k} f(x_i) - f(x^*) \leq \frac{c \cdot L R}{\sqrt{k+1}}, \quad (9)$$

where $c > 0$ is an absolute constant and L is a uniform upper bound for $\|g_x\|$, $x \in Q$. It can be shown that for this class of optimization problems the rate (Eq. 9) cannot be improved uniformly in the dimension of the space of variables [12].

The *dual* subgradient methods are based on the *linear model* of the objective function [13]. Let us choose $\lambda_i \geq 0$, $0 \leq i \leq k$, with $\sum_{i=0}^k \lambda_i = 1$. Then for all $x \in Q$ we have

$$l_k(x) \stackrel{\text{def}}{=} \sum_{i=0}^k \lambda_i [f(x_i) + \langle g_{x_i}, x - x_i \rangle] \stackrel{(6)}{\leq} f(x).$$

One of the variants of the dual method, the *simple averaging scheme*, looks as follows:

$$x_{k+1} = \arg \min_{x \in Q} \left\{ \frac{1}{k+1} \sum_{i=0}^k [f(x_i) + \langle g_{x_i}, x - x_i \rangle] + \frac{L \cdot \|x - x_0\|^2}{2R\sqrt{k+1}} \right\}.$$

In this method, it is possible to approximate simultaneously the optimal solutions of the primal and the dual problems. The earliest versions of the dual methods are also known as *mirror descent schemes* [12]. They allow measurement of distances in non-Euclidean norms. This possibility is especially useful for Q having a simplex structure. All these methods ensure the optimal rate of convergence (Eq. 9).

Another big group of subgradient methods is based on a *piece-wise linear model*. They are called *bundle methods*. Define

$$L_k(x) \stackrel{\text{def}}{=} \max_{0 \leq i \leq k} [f(x_i) + \langle g_{x_i}, x - x_i \rangle] \stackrel{(6)}{\leq} f(x).$$

This function contains *all* information on the objective function accumulated after k iterations. The most straightforward way of using it is implemented in the *Kelley method*

$$x_{k+1} \in \underset{x \in Q}{\text{Argmin}} L_k(x). \quad (10)$$

Unfortunately, this natural strategy has exponentially bad lower complexity bound [14, p. 158]. A more reserved behavior is implemented in the *classical bundle method* [15]. In this scheme, starting from a prox-center x_0 , we construct the following sequence:

$$x_{k+1} = \arg \min_{x \in Q} \{L_k(x) + \frac{1}{2} \gamma_k \|x - x_0\|^2\}, \quad (11)$$

where γ_k are certain proximity parameters. This process is stopped if $f(x_k)$ is sufficiently smaller than $f(x_0)$. In this case, we choose x_k as a new prox-center and start the process again.

For the majority of bundle methods it is possible to prove convergence to the optimal solution of problem (5). However, to the best of our knowledge, no complexity estimates of the classical bundle method are published yet. There exists only one bundle-type method with justified complexity bounds. It

is called the *level method* [16]:

$$\begin{aligned} \lambda_k &= \frac{1}{2} \min_{0 \leq i \leq k} f(x_i) + \frac{1}{2} \min_{x \in Q} L_k(x), \\ Q_k &= \{x \in Q : L_k(x) \leq \lambda_k\}, \\ x_{k+1} &= \pi_{Q_k}(x_k). \end{aligned} \quad (12)$$

Each iteration of this method is quite expensive. However, usually it demonstrates very fast convergence. In the worst-case situation, it has the optimal rate of convergence (Eq. 9).

The last big group of subgradient methods consists of the *cutting plane schemes*. These methods use inequality Equation (7) as a *cutting plane* that divides the whole space on two parts, only one of them containing x^* . Consequently, they are interested in decreasing the “size” of *localization sets*:

$$\mathcal{L}_k = \{x \in Q : \langle g_{x_i}, x_i - x \rangle \geq 0, i = 0, \dots, k\}.$$

For that, we need to put new cutting plane in a properly defined central point of current localization set.

The first straightforward implementation of this idea was done in the *center-of-gravity method* [17]:

$$x_{k+1} = \mathcal{CQ}(\mathcal{L}_k). \quad (13)$$

In view of very heavy computational cost of each iteration, this method is interesting only from theoretical point of view. It was the first nonsmooth optimization method with *linear* rate of convergence:

$$\min_{0 \leq i \leq k} f(x_i) - f(x^*) \leq \left(1 - \frac{1}{e}\right)^{k/n} LR. \quad (14)$$

For a finite dimension, this rate is optimal [12]. The implementable version of this method is given by the famous *Ellipsoid Method*. Assume that $Q = \{x : \|x - x_0\| \leq R\}$ and choose $H_0 = I$, where I is $n \times n$ identity matrix. Then this method works as follows:

$$\begin{aligned} x_{k+1} &= x_k - \frac{R}{n+1} \cdot \frac{H_k g_{x_k}}{\langle H_k g_{x_k}, g_{x_k} \rangle^{1/2}}, \\ H_{k+1} &= \frac{n^2}{n^2 - 1} \left(H_k - \frac{2}{n+1} \frac{H_k g_{x_k} g_{x_k}^T H_k}{\langle H_k g_{x_k}, g_{x_k} \rangle} \right). \end{aligned} \quad (15)$$

This method was invented by Yudin and Nemirovski [18] and rediscovered later by Shor [19]. Method (15) was used by Khachiyan [20] in his famous proof of polynomial-time solvability of linear programming.

At the current moment there exists several cutting plane methods based on different notions of central points of convex sets. Among the most popular schemes are method of *inscribed ellipsoids* [21], *analytic center* method [22,23], and *volumetric center* method [24,25]. For all of them it is possible to prove suboptimal rate of convergence. However, the complexity of each iteration of these schemes is much higher than that of the Ellipsoid method.

SUBJECTIVE PROBABILITY

NABIL I. AL-NAJJAR

Decision Sciences, Kellogg School of
Management, Northwestern University,
Evanston, Illinois

INTRODUCTION

What is probability? Observers of scientific progress in the last few decades will likely find this question puzzling. Modern probability theory is, by all objective measures, a runaway success in shaping modern science. In management sciences, entire fields such as finance, economics, and operations research are in part founded on probabilistic concepts and tools. Yet it is hard to think of other concepts as important as probability whose very meaning remains unclear and, often, controversial.

The formative years of the modern theory of probability, roughly from the 1920s through the 1950s, also witnessed lively debates about its nature and interpretation.¹ The arguments revolved around issues like: Is probability an objective feature of the phenomena under study, or merely a subjective judgment of the decision maker? How is probability related to frequency? If probability is an objective feature of reality, like heat or magnetism, then what scientific experiment could be devised to prove its existence and ascertain its value? If it is, on

the other hand, a decision maker's purely subjective state of mind, then is there a way to judge its reasonableness or consistency with empirical evidence?

Classic works by Doob [15] and Savage [9] sidestepped these philosophical issues by providing elegant mathematical formalisms of the concept of probability and related constructs. The phenomenal growth of modern probability theory and applications owes much to these works, which freed researchers from being bogged down with the hard conceptual issues of an earlier generation.

But, setting foundational questions aside neither implies that these questions have been answered nor that their practical and conceptual implications magically disappear. In fact, we would argue that it is in the management sciences, be it competitive strategy, finance, economics, or game theory, that these foundational questions about the meaning and interpretation of probability have potentially the greatest significance.

To illustrate, consider some elementary issues in the study of competitive strategy:

- *Overoptimism:* Do decision makers (firms, managers, investors) tend to be overoptimistic? If probability judgments are purely subjective, then in what sense could they be wrong, or overoptimistic?
- *Objective versus Subjective Probability:* Relatedly, are some probability judgments more "objective" than others? Is there a sense in which decision makers can separate the objective from the subjective parts of their judgments?
- *Risk versus Uncertainty:* Should decision makers approach one-of-a-kind, highly uncertain decisions like betting on the success of a new disruptive technology in the same way as they approach routine, well-understood risks? More broadly, can one give formal meaning to Knight's [3] distinction between risk (roughly, events with known

¹The classic works include Keynes [1], Borel [2], Knight [3], Ramsey [4], de Finetti [5,6], von Mises [7], Reichenbach [8], and Savage [9]. Galavotti [10] provides a comprehensive overview of the subject; see also Bernstein [11] for a popular account of the notions of risk, uncertainty, and probability. For the early subjectivist views of Ramsey and de Finetti, see Zabell [12], Galavotti [13], and Galavotti [14].

odds) and uncertainty (unknown, or unknowable odds)?

- *Belief Formation, Learning, and Testing*: How should firms translate the past experience into probability judgments to use in future decisions? And, is there a meaningful way to test these judgments against new evidence?

This is a sample of the questions that surface, in different guises, in every major branch of the management sciences. A major task of a formal decision theoretic framework is to provide a systematic way to address (or, as the case may be, dismiss) such questions.

The centerpiece of our survey is Savage's [9] theory of subjective probability, which remains the foundation of the subject till date. We provide an account of its main assumptions and conclusions. Our emphasis is on the interpretation of the axioms, important attempts to extend the theory, possible critiques, and potential limitations.

EXPECTED UTILITY THEORY

von Neumann–Morgenstern Representation

Before discussing Savage's framework,² it is useful to take a detour into von Neumann and Morgenstern's [19] classic representation theory when probabilities are objectively given. In their model, the primitives are a set of consequences: $C = \{\dots, x, y, z, \dots\}$, for example, monetary outcomes, and the set of probability distributions $\mathcal{P}$, or lotteries, on C with finite support. An individual has a preference $\succsim$ over $\mathcal{P}$ that is reflexive, complete, transitive, and (suitably) continuous.³ The crucial ingredient in von Neumann and Morgenstern's theory is the *independence axiom*:

for all lotteries p, q , and z and real number $\alpha \in (0, 1]$

$$p \succsim q \iff \alpha p + (1 - \alpha)z \succsim \alpha q + (1 - \alpha)z.$$

This is an additivity property of the preference: if two compound lotteries, like those on the RHS of the equivalence above, share a common component $(1 - \alpha)z$, then this component can be removed without affecting the ranking of the remaining components p and q .

von Neumann and Morgenstern show that a preference satisfies the axioms if and only if there is a utility function $u : C \rightarrow \mathbb{R}$, unique up to positive affine transformation, such that⁴

$$p \succsim q \iff \int_C u(c) dp(c) \geq \int_C u(c) dq(c). \quad (1)$$

In words, the decision maker ranks lotteries by applying the expected utility criterion with respect to the von Neumann and Morgenstern utility function u . When C is a convex set of real numbers, the utility function u will embed the decision maker's risk attitude.

von Neumann and Morgenstern work laid the foundation for the expected utility criterion, which is central to all subsequent developments in decision theory. A major drawback, however, is that a decision maker in their model is somehow presented with probability distributions to choose from. In most cases of interest, such as in games of strategy or business plans with even moderate degree of realism and complexity, decision makers are not offered the opportunity to choose between gambles with objectively known probabilities. In such situations, the question is: Under what conditions would decision makers behave as if they had "mental models" or "representations" of their environment that take the form of a probabilistic belief to use in applying the expected utility criterion? We turn to this next.

²In addition to Savage's [9] classic work, Fishburn [16] provides a textbook account while Kreps [17] is an excellent, very readable introduction to the subject. Much of our terminology and notation follows Machina and Schmeidler [18].

³This is known as the *Archimedean axiom*. See the references above for precise statement.

⁴Given our assumption that $\mathcal{P}$ consists of distributions with finite support; the integral here is, in fact, a sum. We use the integral notion to emphasize symmetry with similar expressions in other representation theorems.

Savage's Framework

The key ingredients in Savage's theory are

- States: $\Omega = \{\dots, \omega, \dots\}$.

In principle, a state of the world ω is a complete specification of every conceivable aspect of the decision problem at hand. In Savage's words, a state is "a description of the world leaving no relevant aspect undescribed." While this may be a useful conceptualization of states in a foundational work, Savage is, of course, aware of the need for a more parsimonious notion of state in practical problems.⁵

- Events: $\mathcal{E} = 2^\Omega = \{\dots, A, B, E, \dots\}$.

An event E is a set of states. Events will usually refer to the information available to the decision maker; in this case, interpret the event E as the piece of information that "the state belongs to E ." Note that the set of events is the power set 2^Ω , so there is no *a priori* restriction on what set of states can constitute an event. In Savage's framework, such restrictions are part of the objective constraints facing the decision maker, rather than inherent in the framework itself. See the section titled "Feasibility Constraints and Complexity."

- Consequences: $C = \{\dots, x, y, z, \dots\}$.

A consequence x is a complete description of all that is relevant to the decision maker's utility. This usually includes monetary rewards and other measures of material payoffs, but can also contain social and/or psychological factors (such as fairness, guilt, and the like).⁶

⁵Savage refers to these as "small worlds," which are coarsenings of the underlying complete state space.

⁶Savage writes that consequences "might in general involve money, life, state of health, approval of friends, well-being of others, the will of God, or anything at all about which the person could possibly be concerned. Consequences might appropriately be called states of the person, as opposed to states of the world."

- Acts: $\mathcal{F} = \{\dots, f, g, \dots\}$.

An act is a finite-valued function that maps states to consequences. The restriction to finite values is for technical and expository convenience, and is not essential for the theory.

Savage's Axioms

Savage's goal was to derive a representation of a decision maker's choice behavior in which uncertainty is represented by a probabilistic belief about the unknown states. This will, among other things, provide an interpretation of probability as the decision maker's implied degree of belief. Choice behavior is formalized as a preference $\succsim$ on $\mathcal{F}$ (formally, a binary relation on $\mathcal{F} \times \mathcal{F}$). Although in concrete decision problems choice is limited to some exogenously given feasible set of acts $\mathcal{B} \subset \mathcal{F}$, the framework assumes a preference that is defined on all acts and is independent of the particular feasible set.⁷

A crucial methodological aspect of Savage's framework is its focus on observable choices. Cognitive processes and other psychological aspects of decision making matter only to the extent that they have directly measurable implications on choice—at least in principle, and possibly only under idealized or hypothetical experimental or choice settings. The process of decision making—what steps a decision maker takes, or what heuristics he employs—has no formal meaning within the theory. The process is only relevant in so far as it has measurable behavioral consequences, and these are summarized by the preference $\succsim$ in the sense that one can, in principle, offer the decision maker the choice between any two acts f and g , and directly measure what choice he/she makes.

Seven axioms, numbered P1 through P7, characterize preferences that have an expected utility representation. Below we formally state and comment on the most controversial axioms, P1–P4.

⁷Other models of choice, such as the minimax regret criterion proposed by Savage [20], allow dependence on the feasible set.

Axiom P1 [Ordering]. $\succsim$ is complete, reflexive and transitive.

The key part of this axiom is completeness; it requires the decision maker to be able to rank any conceivable C -valued function on the state space, no matter how complex such function may be. Completeness implies that a rational decision maker cannot say: “I am unable to choose between f and g because the evidence available to me is insufficient and/or ambiguous.”

Completeness has been questioned by a number of authors. Bewley [21,22], for example, argues that one should not expect completeness to hold when there is ambiguity about the probabilities. Shafer [23] argued for a constructive interpretation of subjective probability, under which completeness need not hold. Savage’s response to these objections would presumably be that in any real choice in a problem, a decision must ultimately be made, even when the evidence is scant or imperfect.

Axiom P2 [Sure-Thing Principle–STP].

For all events E and acts f, g, h , and h' ,

$$\begin{aligned} \begin{bmatrix} f(\omega) & \text{if } \omega \in E \\ h(\omega) & \text{if } \omega \notin E \end{bmatrix} &\succsim \begin{bmatrix} g(\omega) & \text{if } \omega \in E \\ h(\omega) & \text{if } \omega \notin E \end{bmatrix} \\ \implies &\begin{bmatrix} f(\omega) & \text{if } \omega \in E \\ h'(\omega) & \text{if } \omega \notin E \end{bmatrix} \\ &\succsim \begin{bmatrix} g(\omega) & \text{if } \omega \in E \\ h'(\omega) & \text{if } \omega \notin E \end{bmatrix}. \end{aligned}$$

This is perhaps the most central of Savage’s Axioms. It states that the preference between two acts with a common extension outside some event E does not depend on that common extension. In the formalism above, consequences are determined according to f and g on the event E , and a common act h outside E . The STP (sure-thing principle) then says that the preference remains unaltered if we replace h by some other common extension h' . This amounts to the separability of the preference across events, a necessary

property for it to have an expected utility representation.

The STP cuts in many different ways and has been at the center of most of the controversies in this area. The two classic objections to the Savage framework by Allais [24] and Ellsberg [25] are based on violations of the STP. In the section titled “Information, Dynamic Choice, and Dynamic Consistency,” we note the close connection between the STP and the consistency of dynamic choice.

For the next axiom, we need the following definition: An event E is *null* if any pair of acts which differ only on E are indifferent. Below, identify a consequence x with the constant act that yields x in every state.

Axiom P3 [Monotonicity]. For all outcomes x and y , nonnull events E and acts g ,

$$\begin{aligned} \begin{bmatrix} x & \text{if } \omega \in E \\ g(\omega) & \text{if } \omega \notin E \end{bmatrix} &\succsim \begin{bmatrix} y & \text{if } \omega \in E \\ g(\omega) & \text{if } \omega \notin E \end{bmatrix} \\ \iff &x \succsim y. \end{aligned}$$

Roughly, if a consequence x is preferred to another consequence y , then this is so regardless of the state in which these consequences obtain. Conceptually, this axiom amounts to separating states, which are the object of uncertainty, from consequences, which is what matters for payoffs.

Objections to this axiom appeared in Karni *et al.* [26], Schervish *et al.* [27], and Karni [28], among others.

Axiom P4 [Weak Comparative Probability]. For all events A, B , and outcomes $x^* > x$ and $y^* > y$.

$$\begin{aligned} \begin{bmatrix} x^* & \text{if } \omega \in A \\ x & \text{if } \omega \notin A \end{bmatrix} &\succsim \begin{bmatrix} x & \text{if } \omega \in B \\ x^* & \text{if } \omega \notin B \end{bmatrix} \\ \implies &\begin{bmatrix} y^* & \text{if } \omega \in A \\ y & \text{if } \omega \notin A \end{bmatrix} \\ &\succsim \begin{bmatrix} y & \text{if } \omega \in B \\ y^* & \text{if } \omega \notin B \end{bmatrix}. \end{aligned}$$

Since $x^* \succ x$, the first preference ranking means that the decision maker prefers to bet on the event A rather than B . We would like to interpret this to mean that he/she, therefore, judges A to be more likely than B , an interpretation that is possible only if this likelihood judgments is independent of the specific consequences x^* and x . This is precisely what the axiom asserts.

Savage requires three more axioms, P5 (nondegeneracy), P6 (small event continuity), and P7 (uniform monotonicity).⁸ These axioms are needed primarily for technical reasons, and so they do not carry the substantive weight of the others.

Savage's Subjective Expected Utility Representation

Savage's Representation Theorem [Savage, 1954]. *A preference $\succsim$ satisfies P1-P7 if and only if there is a finitely additive probability measure⁹ P and a function $u : C \rightarrow \mathbb{R}$ such that for every pair of acts f and g :*

$$f \succsim g \iff \int_{\Omega} u(f(\omega)) dP \geq \int_{\Omega} u(g(\omega)) dP. \quad (2)$$

Moreover, P is unique and u is unique up to positive affine transformation.

In words, the theorem says that a decision maker who satisfies the axioms

- reduces all uncertainty about the states to a subjective probability measure P that reflects his beliefs;
- ranks consequences according to a utility function u that reflects his taste;

- evaluates acts according to the expected utility criterion.

Savage's theorem implicitly *defines* probability as the degree of belief implied by the decision maker's choice over uncertain prospects. Probability is not an objective property of the world, but the decision maker's subjective assessment of the likelihood of various events, as expressed in his willingness to make bets on those events. In Savage's framework, it makes no sense to talk about beliefs being "right" or "wrong," overly optimistic or pessimistic, or whether some probabilities may be more "objective" than others.¹⁰

An important implication of the theory is the *separation of tastes from beliefs*. To illustrate this, consider two decision makers who may disagree on how to rank various acts. In principle, their disagreement may have its source in how they assess the likelihood of various events, in their preference over consequences, or some complex interaction between the two. For example, imagine two leaders who may disagree on how to deal with an emerging nuclear threat by a rogue regime. Their disagreement may be the result of different assessment of how likely the regime is to develop weapon-grade fuel, and/or how undesirable it is to have such regime armed with nuclear weapons. Suppose that the two decision makers satisfy Savage's axioms, with P_1, P_2 and u_1, u_2 denoting their subjective beliefs and utilities respectively. Then Savage's theorem separates tastes from beliefs because it asserts that there can be no source of disagreement

⁸P5 asserts the existence of two nonindifferent outcomes, and P6 implies that the subjective belief is atomless (in particular, Ω must be infinite; Gul [29] provides an alternative model with a finite state space). P7 is necessary to handle infinite-valued acts.

⁹See footnote 16 for a brief discussion of the role of finite additivity.

¹⁰Anscombe and Aumann [30] offer a simpler derivation of subjective probability provided one is willing to assume the existence of objective lotteries. Specifically, their acts take values in the space of probability distribution on consequences, $\Delta(C)$, rather than "pure" consequences C as in Savage, and the decision maker is assumed to rank objective lotteries according to expected utility criterion. The key assumption here is an appropriate version of the independence axiom.

beyond differences between either P_1, P_2 and/or u_1, u_2 .¹¹

What is the significance of separating tastes from beliefs? One may argue that both are aspects of the preference $\succsim$ and both are subjective. Intuitively, however, tastes and beliefs are quite different animals. In Aumann's [31] words: "[U]tilities directly express tastes, which are inherently personal. It would be silly to talk about 'impersonal tastes,' tastes that are 'objective' or 'unbiased'. But it is not at all silly to talk about unbiased probability estimates, and even to strive to achieve them. On the contrary, people are often criticized for wishful thinking—for letting their preferences color their judgement. One cannot sensibly ask for expert advice on what one's tastes should be; but one may well ask for expert advice on probabilities."

While Aumann's reasoning is compelling, and undoubtedly shared by many (including the authors), it is important to understand that Savage's theory has nothing to say about judging whether beliefs are reasonable or to test them against evidence. De Finetti points out that a subjective proposition, such as a subjective probability assessment, is one which "no experience can prove [...] right, or wrong; nor, in general, could any conceivable criterion give any objective sense to the distinction [...] between right and wrong."

¹¹In Savage's theory, the separation between tastes and beliefs is a consequence of the fact that the representation identifies P , u , and the way in which they should be combined (the expected utility criterion). Machina and Schmeidler [18] provide an alternative axiomatization—which relaxes the STP but strengthens P4—characterizing preferences that are *probabilistically sophisticated*. As in Savage, these are preferences in which the decision maker has a probabilistic belief P over the state space, and who is indifferent between acts that induce the same distribution on consequences (under P). The difference is that lotteries over consequences are ranked according to a monotone functional; the expected utility criterion is but a special case of such functional. Machina and Schmeidler's [18] theory provides some of the weakest conditions known, separating tastes from beliefs while not requiring expected utility.

[6, p. 174]. The problem of developing criteria for testing beliefs, or to narrow the range of reasonable beliefs based on, say, criteria of simplicity, remains open.

INTERPRETATION AND IMPLICATIONS

Normative Theory and the Definition of "Rationality"

It is hard to argue that Savage's theory and his representation accurately describes all (or even most) instances of how people actually make choices. Classic examples by Allais [24] and Ellsberg [25] show that seemingly reasonable choices may violate the Savage axioms. A parallel development, pioneered by Tversky and Kahneman [32], draws on research in psychology to point out systematic deviations from Savage-style rationality. In a seminal paper, Tversky and Kahneman [32] argue that "people rely on a limited number of heuristic principles which reduce the complex tasks of assessing probabilities and predicting values to simpler judgmental operations. In general, these heuristics are quite useful, but sometimes they lead to severe and systematic errors."¹² In general, the resulting behavior is inconsistent with Savage's theory.

But, if this theory is not descriptive of the way people actually make decisions, then what is its contribution? One answer is that the theory provides an operational *definition* of what we mean by rational behavior, namely, as behavior consistent with the axioms and the expected utility representation (Eq. 2). This is a definition with far reaching consequences both in what it includes as well as what it excludes.

On the one hand, Savage's theory may be seen as too permissive a framework for defining rationality. Any probability measure on the state space, no matter how absurd, qualifies as rational belief. Believers in intelligent

¹²See Kahneman *et al.* [33] for a collection of important contributions to the literature on "heuristics and biases," and Kahneman [34] for a more recent account of the literature, especially, in how it relates to economics and related fields.

design and members of the Flat Earth Society¹³ are rational, provided only that they are consistent with the representation. Savage is simply not in the business of passing normative judgments about what is and what is not a reasonable belief, or how beliefs should be formed. Rather, he seeks criteria for coherence of beliefs “to distinguish between coherent behavior and blunder, or demonstrable incoherence in the face of uncertainty” and it is best thought of as a tool “by which a person can police his own potential decisions for incoherency.” Savage [35, p. 307].

On the other hand, Savage’s theory has powerful consequences in terms of what it rules out as irrational behavior, or as admissible models of such behavior. His framework, among other things: (i) erases any difference between risk and uncertainty; (ii) expresses dynamic decision problems as constrained static problems; and (iii) reduces differences of opinions to either unexplained difference in priors or to differences in information. These and other implications of Savage’s framework are discussed further in this article. Here we illustrate the power of the framework in a particularly simple example.

Consider the following example which appears in Machina [36]: Mom has one indivisible treat to give to one of her two children, Abigail and Ben. Let a, b denote the acts of giving the treat to Abigail and Ben, respectively, and let m denote the act where Mom flips a fair coin and decides to give the treat to Abigail if the coin turns heads and to Ben otherwise. Suppose that $a \sim b$, so Mom is indifferent between giving the treat to one child or the other. Expected utility implies that m should be indifferent to a and b , but it also seems entirely reasonable that $m \succ a \sim b$, the latter ranking indicating that Mom views a coin toss as more equitable, and thus preferable to an arbitrary assignment of the treat. This, on the surface, seems like a perfectly rational behavior that contradicts Savage’s representation.¹⁴

In Savage’s framework, instances of conflict between supposedly rational behavior and the rationality axioms must be accounted for as the result of misspecifying the state space, the set of consequences, or the constraints facing the decision maker. In Machina’s Mom example, the answer is easy: The set of consequences ought to take into account “fairness.” What matters for Mom and the kids is not just who gets the treat, but also whether the procedure is perceived as fair. The original, and apparently paradoxical description of the problem missed an important payoff-relevant aspect: Mom may not be indifferent to the different procedures for allocating the treat, and so the procedure should properly be part of the set of consequences.

Machina [36, Section 6] provides examples and a critical discussion of the approach of change-the-consequences-so-anomalies-disappear, which is presented in the last paragraph. He shows, for example, how enlarging the space of consequences can eliminate the famous “paradox” due to Allais [24]. In a related vein, Geanakoplos *et al.* [37] provide examples and an analysis of “psychological games.” These are strategic situations where payoffs may depend not just on the material consequences, but also on such considerations as fairness, guilt, vindictiveness, and so on.

The upshot of the above discussion is: (i) if the set of consequences (or any other aspect of the model, such as the state space) is misspecified, then there is no reason not to expect violations and anomalies; and (ii) Savage’s framework provides a *methodology* that gives us guidance as to which models or explanations to pursue when we encounter anomalous behavior. In the above example, the framework suggests a misspecification of the set of consequences as the source of the anomaly.

¹³<http://www.alaska.net/clund/edjublonskopf/Flatearthsociety.htm>.

¹⁴Probabilities in this example are objective, in the sense of being exogenously given as part of

the description of the problem. The example can, of course, be readily restated for subjective probability. The point of the example is to illustrate an intuitive contradiction with the reasonableness of the expected utility criterion aspect of Savage’s representation.

Feasibility Constraints and Complexity

Savage's theory assumes a preference (and produces a representation) defined over all acts. In virtually every problem of interest, the decision maker chooses from a set of feasible acts, $\mathcal{B} \subseteq \mathcal{F}$. In this case, the representation identifies the optimal acts given $\mathcal{B}$ as the set.

$$\operatorname{argmax}_{f \in \mathcal{B}} \int_{\Omega} u(f(\omega)) dP. \quad (3)$$

Although feasibility constraints do not formally appear in Savage's representation, his theory has the implication that such constraints must be introduced as exogenous and objective elements of the decision problem. Subjectivity in Savage's theory is limited to the decision maker's taste over consequences, his beliefs over states, and the expected utility form he uses to combine the two. Objective feasibility constraints cannot, within Savage's theory, influence the decision maker's tastes or subjective judgments.

This has important implications. A common, and reasonable, complaint about Savage's theory, for example, Shafer [23], is that a decision framework should take into account the complexity of describing the states, of comparing acts, and so on. At one level, complexity, however defined, can be trivially accommodated within Savage's theory: let $\mathcal{Z} \subset 2^{\mathcal{F}}$ denote the set of all subsets of acts that are consistent with our favorite notion of "simplicity" or computational feasibility, and limit the applicability of Equation (3) to those sets $\mathcal{B} \in \mathcal{Z}$.

The problem with this approach is that in Savage's framework, Equation (3) makes sense only because we start with a preference over all acts and derive a representation which is independent of any cognitive or complexity-based constraints.¹⁵ One might reasonably expect cognitive or computational limitations to constrain the decision maker's preference. But accommodating such constraints in Savage's framework seems to

require a decision maker who starts with a preference that violates them in the first place.¹⁶

Information, Dynamic Choice, and Dynamic Consistency

So what might be reasonable specifications of constraints that limit decision makers' choices in practice? Obvious sources of constraints involve such things as wealth, technology, or regulations. Call these, for lack of a better term, *physical* constraints, so they can be more easily distinguished from *informational* constraints that reflect limited information. The simplest way to introduce limited information in Savage's framework is in terms of a finite information partition $\Pi = \{\pi_1, \dots, \pi_n\}$ on the state space.¹⁷ At a state ω , the decision maker knows only that the state belongs to the partition element $\pi(\omega) \in \Pi$ that contains ω . Limited information can be viewed as constraining the decision maker's choices to the subset of acts $\mathcal{F}_{\Pi}$ that are measurable with respect to Π . An act $f \in \mathcal{F}_{\Pi}$ is a choice that is contingent on the information and can be evaluated in a completely standard way.

¹⁶A related issue is de Finetti's and Savage's insistence on assuming only finite, rather than countable, additivity. It is possible to obtain a representation like Equation 2, as Arrow [39] does, with countably additive probability, but at the cost of restricting attention to, say, a Borel σ -algebra of events, rather than the power set. Savage and de Finetti would object to this on methodological grounds: a decision framework should not blur the separation between structural assumptions about the choice setting and the feasibility constraints facing the decision maker in a particular choice problem. In Savage's framework, imposing measure theoretic or topological structures amounts to restrictions on the set of acts available to the decision maker. These restrictions should be part of the exogenous constraints facing the decision maker, and not as limitations on the scope of his subjective beliefs. See Al-Najjar [40] for further discussion of this point.

¹⁷More sophisticated models represent information via a σ -algebra and, in dynamic settings, an information filtration.

¹⁵Kopylov [38] provides an extension of Savage's theory to more general domains of events that need not be algebras.

Although Savage's original formulation is *timeless*, the above makes it possible to reinterpret it as a choice problem that takes place over time. Think of the problem as consisting of an *ex ante* stage, where acts are evaluated according to the representation (2), and an *ex post* stage, where partial information about the state is revealed. Suppose this information takes the form that the state lies in some component π of the finite partition Π . Then the STP essentially amounts to saying that the *ex ante* preference $\succsim$ gives rise to a well-defined conditional preference $\succsim_\pi$ that is dynamically consistent in the sense that, roughly, the conditional ranking over acts agrees with the *ex ante* ranking.¹⁸ Epstein and Le Breton [41] show that dynamic consistency is essentially equivalent to a weakened version of the STP. In particular, models of ambiguity aversion (e.g., multiple prior models) cannot be dynamically consistent in any plausible sense (see the section titled "Risk versus Uncertainty").¹⁹

The fact that Savage's framework can so effortlessly accommodate limited information is one of its crucial advantages. Without this it would be hard to imagine how the development of games with incomplete information [44], dynamic games of all types, and models of knowledge and interactive decision making [31,45] could have proceeded.

What makes this formulation of dynamic choice so attractive is its tractability: dynamic choice is nothing more than static choice subject to informational constraints. As noted by some authors (Kreps [17,46], for instance), this reduction to static choice seems to be missing intuitively important aspects of dynamic behavior we would care about as modelers in understanding games, political contests, or business strategy.

¹⁸Formally, the complement of π is null under $\succsim_\pi$, and for any two acts f and g that agree outside π , $f \succsim g$ if and only if $f \succsim_\pi g$.

¹⁹See also Karni and Schmeidler [42]. Wakker [43] discusses another issue related to dynamic consistency, namely aversion to information that could result when the expected utility criterion is violated.

Risk versus Uncertainty

The distinction between situations where probabilities are known and ones where there is insufficient information to form a probability judgment seems, at an intuitive level, meaningful. Most people think of coin tosses, dice throws, or routine insurance losses as well-understood actuarial risks governed by objective probabilities. This is in contrast with events like "there will be a terrorist nuclear attack within the next 10 years," or "my competitor will respond to my new product introduction with a price cut," where there does not seem to be an obvious probability assignment. Knight [3] and Keynes [47] distinguish between situations of risk, where probabilities are well-understood, and problems involving uncertainty.²⁰ While this distinction seems, at some levels, quite intuitive, it has no meaning within Savage's theory. Put differently, a decision maker in this theory reduces all uncertainties to risks, in the sense that he treats all uncertain prospects in the same way, namely by evaluating them using the expected utility criterion with respect to his subjective probability measure.

²⁰Keynes [47] explains the difference as follows: "By 'uncertain' knowledge, let me explain, I do not mean merely to distinguish what is known for certain from what is only probable. The game of roulette is not subject, in this sense, to uncertainty; nor is the prospect of a Victory bond being drawn. Or, again, the expectation of life is only slightly uncertain. Even the weather is only moderately uncertain. The sense in which I am using the term is that in which the prospect of a European war is uncertain, or the price of copper and the rate of interest 20 years hence, or the obsolescence of a new invention, or the position of private wealth-owners in the social system in 1970. About these matters there is no scientific basis on which to form any calculable probability whatever. We simply do not know. Nevertheless, the necessity for action and for decision compels us as practical men to do our best to overlook this awkward fact and to behave exactly as we should if we had behind us a good Benthamite calculation of a series of prospective advantages and disadvantages, each multiplied by its appropriate probability, waiting to be summed."

Bewley [21,22], Schmeidler [48], and Gilboa and Schmeidler [49] extend the framework to allow for such distinction. Bewley relaxes the completeness part of P1 so the decision maker may be unable to rank some pairs of acts. He assumes that von Neumann–Morgenstern independence axiom holds over the set of acts on which his preference is complete. His main theorem represents such preferences as follows: There is a compact convex set of probability measure $\mathcal{P}_B$ and a von Neumann–Morgenstern utility function u such that

$$\begin{aligned} f \succsim g &\iff \int_{\Omega} u(f(\omega)) dP \\ &\geq \int_{\Omega} u(g(\omega)) dP, \quad \forall P \in \mathcal{P}_B. \end{aligned} \quad (4)$$

In words, f is preferred to g if and only if there is unanimity among all measures in $\mathcal{P}_B$ on how to rank them. When the set $\mathcal{P}_B$ is a singleton, this reduces to standard subjective expected utility (which must, of course, be complete). A nonsingleton $\mathcal{P}_B$ represents uncertainty, or ambiguity, about the “true” probability and will lead to incompleteness. The unanimity criterion in Equation (4) is a robustness requirement under which the decision maker ranks acts only when such ranking is insensitive to how the “true” prior varies within $\mathcal{P}_B$.

Gilboa and Schmeidler [49] also develop a representation involving a convex set of priors.²¹ Rather than weakening completeness, Gilboa and Schmeidler [49] weaken the independence axiom (essentially, the STP) to obtain the following representation: there is a compact convex set of probability measure $\mathcal{P}_{GS}$ and a von Neumann–Morgenstern utility function u such that

$$\begin{aligned} f \succsim g &\iff \min_{P \in \mathcal{P}_{GS}} \int_{\Omega} u(f(\omega)) dP \\ &\geq \min_{P \in \mathcal{P}_{GS}} \int_{\Omega} u(g(\omega)) dP. \end{aligned} \quad (5)$$

²¹In Schmeidler’s [48] model, beliefs are represented as a capacity and the decision maker evaluates acts using the Choquet integral. These preferences overlap with those introduced in Gilboa and Schmeidler [49].

That is, each act f is evaluated according to the worst measure $P_f \in \mathcal{P}_{GS}$ for that act. Again, this reduces to Savage-style representation if the set $\mathcal{P}_{GS}$ is a singleton, in which case the preference must satisfy independence. However, when independence is violated (and their other axioms hold), the set $\mathcal{P}_{GS}$ is nonsingleton, and the resulting preference displays pessimism or caution. Gilboa–Schmeidler theory draws some of its motivation from the desire to reproduce choice patterns consistent with those appearing in the Ellsberg [25] paradox. Their representation has been used to fit anomalies in asset pricing (starting with Dow and Werlang [50]) and macroeconomics (see Hansen [51] for a recent example).²²

As attempts to capture ambiguity or uncertainty, Bewley’s [21,22] and Gilboa and Schmeidler’s [49] representations suffer from significant problems. Bewley’s model cannot answer the obvious question: What should the decision maker do when he faces a choice between two acts f and g that are not ranked according to his criterion? Interesting cases of ambiguity arise precisely when a decision maker has to choose between, say, two business plans about which he lacks precise priors. Presumably, the decision maker must ultimately make a choice, yet Bewley’s theory is silent on what this choice should be. It may be useful to think of Bewley’s model as corresponding to a different revealed preference experiment: while Savage envisions a setting where the decision maker is *forced* to make a choice when confronted with any feasible set $\mathcal{B}$, Bewley’s model is best thought of as recording the choice this decision maker would *voluntarily* make.

The problems with Gilboa and Schmeidler’s [49] model are different and potentially more serious. It is well known, and can be easily demonstrated by example, that their model cannot admit any plausible form of dynamic consistency of choice. See Epstein

²²See Al-Najjar and Weinstein [52] for a critique of these efforts in the special issue of *Economics & Philosophy* on ambiguity aversion, and the replies to their paper in that same issue.

and Le Breton’s [41] paper, titled “Dynamically Consistent Beliefs must be Bayesian.” Arguments concerning the tension between their maxmin criterion (Eq. 5) and consistent dynamic choice are discussed at length in Al-Najjar and Weinstein [52].

It is interesting to note that neither Bewley nor the Gilboa–Schmeidler models appear to capture Knight’s [3] intuition of what uncertainty is about: “[W]e must observe at the outset that when an individual instance only is at issue, there is no difference for conduct between a measurable risk and an unmeasurable uncertainty. The individual, as already observed, throws his estimate of the value of an opinion into the probability form [...] and ‘feels’ toward it as toward any other probability situation.” This quote of Knight, and Keynes’ description of uncertainty in footnote (20), seems to imply that uncertainty is inherently about dynamic choice, while the Bewley and Gilboa–Schmeidler’s models produce uncertainty-sensitive behavior even in a single, static choice problem. This suggests that their representations capture a different type of behavior than what either Knight or Keynes had in mind.

Exchangeability, Objectivity, and Frequencies

As pointed out earlier, probability judgments in Savage’s theory are purely subjective; there is no sense in which some probabilities are more “objective” than others. Intuitively, however, subjective probabilities should, somehow, be grounded with objective facts, such as the frequencies of outcomes obtained in repetitions of the similar experiments. De Finetti’s notion of exchangeability and his famous representation make it possible to integrate a decision maker’s subjective judgment with objective frequencies. Our exposition here follows Kreps [17] (who considers “De Finetti’s theorem as the fundamental theorem of (most) statistics.”)

Suppose that an experimental scientist or a statistician conducts (or passively observes) a sequence of experiments with outcomes in some set S (so the state space has the product structure $\Omega = S \times S \times \dots$). To pool information across experiments, the observer must assume, in one way or another, that the

experiments are, in a sense, “similar.” De Finetti’s concept of exchangeability formalizes this intuition of similarity and its role as guide in decision making. Roughly, a decision maker subjectively views a set of experiments as *exchangeable* if he treats the indices interchangeably.²³

Different experiments will typically result in different outcomes due to the influence of a multitude of poorly understood or unmodeled factors. Nevertheless, a decision maker’s subjective judgment that the experiments are exchangeable amounts to believing that they are governed by the same underlying stochastic structure. De Finetti’s celebrated theorem says that a probability distribution P on Ω is exchangeable if and only if it has the parametric form

$$P = \int_{\Theta} P^{\theta} d\mu(\theta). \quad (6)$$

Here the parameter set Θ indexes the set of all i.i.d. distributions P^{θ} with marginal θ , and μ is a probability distribution on Θ .

The decomposition (Eq. 6) says that a decision maker subjectively views the experiment as exchangeable if and only if he believes the outcomes to be i.i.d. with parameter θ whose distribution is given by a subjective belief μ . Since the i.i.d. parameters may also be interpreted as limiting frequencies, the representation can be equivalently stated as: a subjective belief P is exchangeable if and only if it can be expressed as distribution on limiting frequencies.

Chew and Sagi [53] show that a form of event exchangeability (plus other weak axioms) implies probabilistic sophistication. De Castro and Al-Najjar [54] isolate the implications of exchangeability assuming only that the preference is monotone, transitive, and continuous, but otherwise incomplete and/or fail probabilistic sophistication. Their motivation is that De Finetti’s

²³ Somewhat more formally, exchangeability means that the decision maker ranks as indifferent an act f and the act $f \circ \pi$ that pays f after a finite permutation of the coordinates π is applied. In particular, he considers an outcome s to be just as likely to appear in the i th as in the j th experiment.

representation simultaneously identifies the relevant parameters *and* Bayesian beliefs about them. On the other hand, the idea of similarity of experiments and the concept of parameters are meaningful even if expected utility is not assumed. De Castro and Al-Najjar [54] develop a subjective version of the ergodic theorem which takes as primitive preferences, rather than probabilities (as in standard ergodic theory). They use this ergodic theorem to show decomposition into i.i.d. parameters without necessarily assuming that the preference is expected utility.

CONCLUDING REMARKS

In his famous reply to calls to abandon a theory due to its anomalies and unintuitive implications, Hilbert said that “No one will drive us from the paradise which Cantor created for us.” Savage has created a “paradise” where important ideas, and even entire fields, could flourish. It is hard to conceive of modern game theory, industrial organization, mechanism design, auction theory, models of incomplete information, bargaining theory, portfolio theory, and option pricing without uncertainty and the use of probabilistic methods to reason about it. Savage has given us a broad license to reduce all uncertainty to risks that can be quantified using probability.

We argued above that one should set aside critiques of Savage that are based on misunderstanding or too narrow an interpretation of his framework. Often the failure is to recognize that Savage’s axioms are not substantive statement subject to refutations by experimental or psychological evidence. Rather, they should be viewed as an organizing methodology that guides and constrains our modeling of choice under uncertainty. By this standard, more than half century after its introduction, Savage’s theory is an unqualified success. Yet, there is a sense that something was lost in the bargain, since we must give up the ability to talk about such things as the difference between risk and uncertainty, “true” dynamic choice, or to have a meaningful theory of belief formation. These are promising direction for future research.

SUPPLIER SELECTION

DAMIAN R. BEIL
Stephen M. Ross School of Business,
University of Michigan, Ann Arbor,
Michigan

Today the average US manufacturer spends roughly half its revenue to purchase goods and services [1]. This makes a company's success dependent on its interactions with suppliers. The role of procurement managers (buyers) within companies has become extremely important, often involving staggering dollar values: a recent cross-industry survey of companies—in areas ranging from aerospace to semiconductors—placed companies' average total spend per procurement employee at \$115 million [2].

With so much of a company's money on the line, and increasing reliance on outsourcing of many complex services and products, the job of a buyer is not only important but also challenging. Buyers must define and measure what "best value" means for the buying organization, and execute procurement decisions accordingly. To identify best value, the buyer must interface with technical, legal, and operations experts within the buyer's company, and act as an expert negotiator and coordinator across many internal and external parties.

Supplier selection is the process by which the buyer identifies, evaluates, and contracts with suppliers. The challenges mentioned above make supplier selection a fertile topic for operations and management science disciplines. There is also a growing audience for such research, as the importance of fostering talent by employing buyers with analytical expertise, general management backgrounds, and deep knowledge in a particular purchasing category becomes widespread [3].

This article is organized around the major steps involved in supplier selection. First, the buyer must identify qualified potential suppliers, as described in the section titled "Identifying Potential Suppliers." Next, the

buyer must evaluate these suppliers. This process is initiated when the buyer formally solicits information from suppliers, as described in the section titled "Information Requests to Suppliers." Depending on the information request, suppliers respond by providing "bids" for the contract, specifying an offer on the contract terms, such as price, lead time, and quality. Various contract terms, which relate to the type of contract up for bid, are overviewed in the section titled "Contract Terms." Suppliers' offers often evolve over the course of negotiation with the buyer, and negotiation processes are touched on in the section titled "Negotiation Process." Finally, as discussed in the section titled "Supplier Evaluation and Contract Award," the buyer determines which supplier or suppliers will be awarded a contract and subsequently monitors the supplier during the life of the contract to support future supplier selection iterations. Finally, the section titled "Supplier Selection Research" discusses ORMS research on supplier selection. While this article introduces the key steps in supplier selection, further readings in this encyclopedia can provide a more detailed picture. Pointers to such readings are suggested throughout this article; most importantly, see section titled "Vehicle Routing and Scheduling" in this encyclopedia for details on procurement contracts and sections titled "Game Theory" and "Game Theory: Extension and Development" in this encyclopedia for discussions about negotiations.

For consistency in the article we refer to "buyers," but in practice the role we describe is also called *procurement manager*, *procurement agent*, or *contracts manager*. This article focuses on the complexities and frictions involved in supplier selection (verifying that suppliers are indeed qualified, using historical supplier performance in making award decisions, etc.). Such complexities are present in the supplier selection process for most goods and services. One possible exception is raw materials traded via commodity exchanges; such markets

are specifically designed to circumvent the complexities and frictions of supplier selection by instituting highly standardized contract terms, using liquid markets to find prices, and using clearinghouses to guarantee the terms of trade. As such, commodity exchanges will not be covered in this article.

IDENTIFYING POTENTIAL SUPPLIERS

To survive in the intensely competitive global economy, it is often critically important to not only develop existing suppliers but also to discover new suppliers. This section outlines the process of finding viable new suppliers. The section titled “Importance of New Suppliers” first briefly motivates why a buyer might wish to find new suppliers. The section titled “Reasons for Supplier Qualification Screening” explains why identifying suppliers is only part of the challenge—the buyer must also be cognizant of the need to ensure that such suppliers are qualified. Supplier qualification screening processes are discussed in the section titled “Supplier Qualification Screening Process.” Because identifying and qualifying potential suppliers can be time consuming and costly, buyers often develop a long-term supply base consisting of qualified suppliers, as discussed in the section titled “Creating a Supply Base.”

Importance of New Suppliers

Several factors make new suppliers important. First, there may exist new suppliers who are superior in some way to a firm’s existing suppliers. For example, a new supplier may have developed a novel production technology or streamlined process, which allows significant reduction in the production costs relative to predominate production technology or processes. Or, a new supplier may have a structural cost advantage over existing suppliers, for example, due to low labor costs or favorable import/export regulations in its home country. Second, existing suppliers may go out of business, or their costs may be increasing. Third, the buyer may need additional suppliers simply

to drive competition, reduce supply disruption risks, or meet other business objectives such as supplier diversity (see the section titled “Contract Award”). In recognition of these reasons, buyers and their internal customers may be obliged by company policy to locate a minimum number of viable, potential suppliers for every product or service procured.

Reasons for Supplier Qualification Screening

Finding a viable new supplier is challenging mainly because of the need to verify the supplier’s ability to meet the buyer’s myriad requirements [4]. Supplier nonperformance on even the most basic level, and for the simplest commodity, can have dire consequences for the buyer, as recounted in the following nursery rhyme:

For want of a nail the shoe was lost. For want
of a shoe the horse was lost.
For want of a horse the rider was lost. For
want of a rider the battle was lost.
For want of a battle the kingdom was lost. And
all for the want of a horseshoe nail.

While apocryphal, the “for want of a nail” message holds a surprising degree of relevance for today’s complex, global supply chains. Boeing’s 787 Dreamliner production schedule was significantly affected by shortages of fasteners, essentially bolts that secure sections of the fuselage together [5]. In consumer products many product safety issues have been traced back to suppliers failing to meet a buyer’s requirements, resulting in dangerous lead paint in toys [6], unsafe car tires [7], and pet food containing poisonous chemicals [8].

Production delays due to parts shortages and recalls of faulty products produced by noncompliant suppliers have cost buyer firms millions of dollars through recalls, warranty costs, and associated inventory adjustments, and have inflicted untold damage on their reputations and future sales potential. Menu Foods’ market capitalization was halved after the firm recalled its pet food in March 2007; its suppliers are suspected of mixing toxic melamine into their wheat gluten in an effort to make it appear more protein rich [9].

New Jersey-based tire importer Foreign Tire Sales traced field failures of its tires to an unauthorized design change made by its supplier, whose design engineer decided to omit gum strips, apparently unaware of their role in preventing tread separation [7]. A surprised Foreign Tire Sales was forced by US government authorities to recall a quarter of a million tires, and risked bankruptcy as a result [10].

Supplier Qualification Screening Process

To avoid the dire outcomes of supplier non-performance, buyers typically take proactive steps to verify a supplier's qualifications prior to awarding them a contract. The primary goal of "supplier qualification screening" is to reduce the likelihood of supplier nonperformance, such as late delivery, nondelivery, or delivery of nonconforming (faulty) goods. A secondary goal is simply to ensure that the supplier will be a responsible and responsive partner in the day-to-day business relationship with the buyer [4]. Supplier qualification screening involves many aspects, which are outlined below.

Reference Checks. The buyer may contact previous customers and ask about the supplier's delivery performance, adherence to contract terms, what (if any) problems arose and how they were resolved, and so on.

Financial Status Checks. The buyer may use published supplier ratings (e.g., Dunn and Bradstreet) to determine the supplier's financial status and likely financial viability in the short to medium term. For example, if the supplier has recently assumed significant debt, this may raise red flags about the possibility that the supplier will declare bankruptcy before fulfilling its obligations to the buyer.

Surge Capacity Availability. The supplier's capacity to increase delivery quantities within short lead times is important as the buyer may be uncertain about their exact quantity needs over the life of the contract. This is particularly true for long-term contracts where demand for the buyer's product may be heavily tied to unforeseen market events (e.g., demand for an airplane manufacturer's products are highly dependent on the

overall economy, which in turn periodically goes through periods of growth and contraction). Surge capacity is available when a supplier has access to second or third shifts, overtime, underutilized facilities, and so on.

Indications of Supplier Quality. The buyer might require that suppliers have ISO 9000 certification (or similar), indicating that the supplier has policies, procedures, documentation, and training in place to ensure continuous adherence to quality standards. However, in some cases the certification documents can be misleading and/or easily forged [4]. To actually see if an adequate level of quality is achievable, the buyer may have to look deeply into the supplier's organization to ensure that the supplier is capable and competent to meet the buyer's specifications.

Ability to Meet Specifications. To rigorously check the supplier's capabilities the buyer might (i) request samples of supplier products and test them to ensure conformance to the buyer's requirements; (ii) visit the supplier's production facility and interview line workers and engineers to ensure that all members of the supplier team understand the critical features of the product in their charge. For example, a buyer seeking to purchase tires from a supplier may interview the design engineers to ensure that they understand each aspect of the tire's design (for instance, the role of gum strips in preventing tread separation at high speeds); and (iii) audit the production facilities to ensure that production can and will only proceed in a manner approved by the buyer. For instance, the buyer may require the supplier to restrict their production to small batch sizes in order to prevent contamination outbreaks from spoiling the entire production run.

Buy-in from Internal Customer(s). Because the buyer typically acts on behalf of an internal customer within the buyer's organization, buy-in from this internal customer is a crucial step prior to contracting. For example, suppose the buyer is purchasing a complex circuit board on behalf of the engineering department (which owns responsibility for this component). To ensure that the internal customer has confidence in the supplier and is willing to work with the supplier, the buyer

will set up meetings between the buyer firm's engineers responsible for the part and the supplier's engineers who would be responsible for producing it.

Supplier qualification processes are costly and can be time consuming. As described above, the processes can involve travel to distant supplier sites. Interviews with suppliers and suppliers' customers are time consuming. Moreover, the entire process involves not only the buyer but also internal customers throughout the buyer organization. Consequently, qualification can take weeks or months—even for commodity-type parts such as printed circuit boards.

Creating a Supply Base

Suppliers who have passed the qualification requirements and are eligible for contract award are commonly referred to as *prequalified* suppliers. If the buyer utilizes short-term contracts and frequently reprocures the same item, it typically makes sense to establish a cohort of prequalified suppliers who will compete for these contracts. Even if the buyer uses long-term contracts for individual items (meaning contracts for individual items are infrequently rebid), it might still make sense to use a prequalified supply base: if the supply base members can potentially supply many different items, they can compete to produce whichever item's long-term contract is up for rebidding. Finally, using a supply base not only reduces qualification screening costs but also allows for the development of standardized contracts and terms and conditions for prequalified suppliers, thereby streamlining administrative processes involved in contracting.

INFORMATION REQUESTS TO SUPPLIERS

Once the buyer has identified potential suppliers, the next step in supplier selection is to formally request that the suppliers provide information about their goods or services. While there is no agreed-upon terminology, generally the buyer makes one of three types of information requests to suppliers. The request types, each appropriate for a different situation, are described below.

Request for information (RFI) is issued when the buyer seeks to gain market intelligence regarding what alternatives and possibilities are available to meet the buyer's needs. Typically, the buyer asks suppliers what goods and services they could potentially provide, what differentiates them from other vendors in the marketplace, and so on. With an RFI the buyer does not state a particular intention to award a contract. However, since responding to an RFI is time consuming for suppliers, generally, suppliers will only respond to the RFI if they expect that the buyer will eventually issue a request for proposal (RFP) or a request for quote (RFQ), which are discussed below.

Request for proposal (RFP) is issued when the buyer has a sense of the marketplace and has a statement of work containing a set of "performance" requirements that the buyer needs fulfilled. For example, the RFP may describe a formed part with certain strength, flexibility, and fire-resistance requirements, but not specify the particular composition of the material. Suppliers respond to the RFP with details on how they would satisfy the buyer's performance requirements and the price they would be willing to accept to do so. Upon learning the supplier's proposed pricing, the buyer may revise its requirements and/or negotiate exact terms with suppliers. Thus, the process is generally iterative. An RFP is appropriate for procurement of items that are nonstandard or highly complex, requiring supplier input and expertise about the best way to meet the requirements set forth in the RFP.

Request for quote (RFQ) is issued when the buyer can develop a statement of work that states the exact specifications of the goods or service needed. This is the case, for example, if the buyer seeks a part made of a particular plastic and formed to a specific set of thickness, density, and shape specifications. RFQs are often used in conjunction with highly structured competitive tendering processes. Typically there is no need for detailed negotiations with suppliers after bid receipt, as lowest price or some other objective criterion is used to evaluate bids. Owing

to their up-front specification requirements, RFQs are appropriate for procurement of items that are standard and well known in the marketplace. For example, in the electronics industry this would include commodity components such as cables, connectors, and circuit boards.

CONTRACT TERMS

The supplier selection process culminates in a contract between the buyer and one or more suppliers. The information received from suppliers via the requests described in the section titled “Information Requests to Suppliers” must ultimately be translated into formal contractual terms before contracting can occur. A contract with a supplier specifies what the supplier should do and how they will be paid by the buyer. At the highest possible level, contract terms relate to either monetary transfers (payment terms) or how the contract will be executed (nonpayment terms). Contracts can specify any number of payment and nonpayment arrangements. A few common ones are listed here to provide the reader with a sense of what types of contract terms the buyer might consider during negotiations and when making a contract award decision. The choice of the particular contract structure (long-term or short-term, fixed-cost or cost-plus, etc.) is beyond the scope of this article, but procurement contracts are covered in detail in the section titled “Vehicle Routing and Scheduling”.

Payment Terms. In a fixed-price contract, the price term specifies what the supplier will be paid regardless of the actual cost to execute its contractual obligations. In a cost-plus contract, a formula is specified, which determines how much the supplier will be paid; for example, under a cost-plus contract the supplier could receive a fixed percentage (e.g., 107%) of the total cost incurred or simply receive payments for time and materials. Various payments can also be specified as contingent on certain actions by the supplier (these can also take the form of penalties). Examples include a payment made only upon delivery or upon maintaining a certain target

inventory service level, an award fee granted for meeting budget targets in a cost-plus contract, an award fee for completing the project within a certain timeline, and so on. Liquidated damages clauses [11] can be used to specify an amount that either the buyer or supplier must pay to the counterparty upon breaching the contract.

Nonpayment Terms. The contract can specify all kinds of details related to how the contract will be executed, for instance, delivery quantities, delivery frequencies, delivery locations, service level, quality level, technical specifications, duration of the contract, and so on. Contracts where goods must be transported typically assign “incoterms” [12] defining the precise point at which the buyer takes control of the shipment (and hence the associated costs and risks).

NEGOTIATION PROCESS

As we will discuss in the section titled “Supplier Evaluation and Contract Award,” when making contract award decisions the buyer considers each supplier’s qualifications as well as the contract terms they offer (e.g., price). A supplier’s qualifications are generally considered exogenous, for example, a supplier’s reputation is based on historical performance and is not alterable in the short term. Contract terms, on the other hand, can be “negotiable” between the buyer and supplier. In a negotiation the buyer attempts to induce favorable terms from suppliers, and likewise, the suppliers attempt to induce favorable terms from the buyer. There are many different possible negotiation processes. This section overviews a few canonical negotiation processes, but a detailed discussion is reserved for the sections titled “Game Theory” and “Game Theory: Extension and Development” of this encyclopedia. For convenience we adopt the viewpoint of a buyer when discussing negotiations.

For better or worse, negotiations are often viewed as zero-sum games where the buyer gains what the supplier gives up. An extreme example of this is the *take-it-or-leave-it offer* approach whereby a powerful buyer essentially dictates the terms to the suppliers. For

instance, the buyer might demand a certain price and simply refuse to consider the supplier unless they agree to this price.

Take-it-or-leave-it offers are rather draconian, and buyers may be reluctant to utilize them for short-term gains if suppliers perceive them as unfair. Furthermore, take-it-or-leave-it offers require the buyer to credibly commit to not renegotiate with the supplier should the supplier choose to reject the buyer's offer. If the buyer cannot make such a commitment, the threat imputed in a take-it-or-leave-it offer is meaningless.

Competitive tendering is an alternative way to extract concessions from suppliers whereby suppliers are played off one another. Typically, suppliers simultaneously submit bids (in response to an RFP or RFQ). Competitive tendering approaches differ in the amount of visibility that suppliers have regarding competitors' bids. At one extreme is the dynamic open-descending bid format. In this format, suppliers see all bids submitted and can respond by lowering their own bid, until all but one bidder has dropped out [typically bidding lasts an hour or so, [13]]. At the other extreme is the sealed-bid format in which each bid is known only to the buyer and the supplier who submitted it. The US government's competitive tendering is typically done through sealed bidding.

It is also possible that the buyer can utilize neither competition nor take-it-or-leave-it offers. Instead, the buyer and a single supplier might *bargain* in some general and unstructured way. Negotiation processes in practice may combine take-it-or-leave-it offering, competitive tendering, and bargaining. For instance, the buyer could employ price-based competitive tendering with a reserve price (the reserve price imposes an upper bound on the amount the buyer is willing to pay for the contract and thereby acts like a take-it-or-leave-it offer) to home in on the most promising supplier, then bargain with this supplier to finalize the contract terms.

Negotiations do not always take a zero-sum approach. The buyer and supplier can potentially both benefit if they realize that their incentives are aligned rather than in conflict. Research to help buyers and

suppliers realize shared interests has led to numerous advances in software-enabled "expressive bidding" in combinatorial auctions; see *The Graph Model for Conflict Resolution*. For instance, in transportation auctions for truckload procurement, both the shipper (buyer) and the carrier (supplier) benefit if the shipper's lanes up for bid complement the carrier's existing transportation networks in a way that minimizes empty truck movements (e.g., see Ref. 14 and references therein).

SUPPLIER EVALUATION AND CONTRACT AWARD

This section describes how the buyer evaluates suppliers, determines the contract winner(s), and performs follow-up monitoring to inform future supplier selections. Supplier evaluation is the process by which the buyer rank orders the suppliers, as described in the section titled "Supplier Evaluation." The buyer then uses this rank ordering, along with other business considerations, to determine which supplier(s) will be awarded the contract, as described in the section titled "Contract Award." Finally, after contract award the buyer can monitor supplier performance and use this information during future supplier selection processes as described in the section titled "Supplier Monitoring."

Supplier Evaluation

The buyer begins the supplier evaluation process by identifying the "dimensions" it wishes to use when evaluating suppliers. Thanaraksakul and Phruksaphanrat [15] surveyed 76 papers on supplier selection in the purchasing literature and found that price, quality, and delivery were the most commonly listed supplier evaluation dimensions. Additional dimensions are also used. Thanaraksakul and Phruksaphanrat [15] provide an extensive list of such dimensions, categorized by prevalence in the purchasing literature. Frequently appearing dimensions include production capacity and flexibility, technical capabilities and support, information and communication systems, financial

status, and innovation and R&D. Dimensions that appear with moderate frequency in the literature include quality systems, management and organization, personnel training and development, performance history, geological location, reputation and references, packaging and handling ability, amount of past business, warranties and claim policies, procedural compliance, attitude and strategic fit, labor relations record, and desire for business. Of course, buyers often employ new dimensions in response to prevailing business issues and challenges. Dimensions that have emerged recently include environmental and social responsibility, safety awareness, domestic political stability, cultural congruence with the buyer organization, and terrorism risk. See Ref. 15 and the literature cited therein for more details.

Once suitable dimensions are identified, the ability to rank order suppliers is crucial for reaching an informed supplier selection decision. Rank ordering is simple when supplier bids are differentiated by a sole dimension such as price. This might be the case, for example, if the buyer has issued an RFQ for a highly standardized component delivered in a certain quantity by a certain date and suppliers are asked to respond with their price for the contract. However, rank ordering suppliers becomes complex when bids must be evaluated across multiple dimensions. For example, if the buyer wishes to evaluate suppliers' bids on the dimensions of price *and* lead time, the buyer must construct a trade-off between these two dimensions to determine whether it prefers, say, a bid with a high price and short lead time to a bid with a low price and long lead time. The challenge of supplier evaluation lies in constructing this trade-off in a way that accurately reflects the buyer's preferences.

Research addressing this challenge dates back by decades. A detailed review is beyond the scope of this article but is provided in Ref. 16. A variety of methodologies are proposed in this literature, but the overall approach is usually one of three types. The first approach is to capture the trade-offs with a simple relationship between the dimensions, for example, a linear function of the dimensions. This is simple, transparent,

and is often used in practice for these reasons. However, the simplicity of this approach has a downside: the buyer can find it difficult to construct weights that truly reflect its preferences. The second approach is to go beyond simple weighting in order to reflect the buyer's preferences with more detailed models. For instance, the buyer can value lead time using inventory models from ORMS and then trade this valuation off against the price offered by the supplier. This approach is less transparent, which makes it more difficult to implement in practice. Success has been enjoyed, particularly in domains in which the trade-offs are relatively clear but how to evaluate them is not—for example, a multiproduct buy in which suppliers can produce subsets of items and offer quantity discounts over the entire order. In such cases, OR tools like mathematical programming can be quite beneficial. Finally, a third approach recognizes that buyers at times find it difficult to articulate their preferences in a quantitative way and answers this difficulty by proposing ways to infer quantitative preferences over attributes by observing the buyer's qualitative choices between options involving these attributes.

Contract Award

Once the buyer has a sound methodology for evaluating suppliers, the process of contract awarding can begin. During this phase the buyer determines which supplier or suppliers to award a contract to. Supplier evaluation is a key ingredient in this process, but award decisions can hinge on more than just how the buyer evaluates the supplier.

For example, even if suppliers are closely matched, the buyer may choose to award the contract to just one of them. *Sole award* contracting may be favorable if the scope of work is best accomplished by a single supplier. For example, the contract may require significant capital investments on the part of the supplier and/or buyer, creating strong economies of scale. Sole-award contracting may also be used if it is unduly costly or risky to deal with multiple suppliers. For example, the buyer may be sourcing an item with intellectual property value (e.g., fabricating a

proprietary part) and need to closely monitor the supplier to prevent leakage of this intellectual property. A buyer outsourcing sensitive back-office operations (e.g., processing of client data) may need to invest a tremendous amount to train its supplier to ensure robust security measures.

Likewise, even if one supplier dominates another, the buyer might choose to give business to both of them. *Multiple-award* contracting can be useful if the buyer wishes to diversify its supply sources to mitigate disruption risks, or if suppliers have insufficient capacity or reverse economies of scale. There are also more strategic reasons for multi-sourcing. For example, a buyer might wish to prevent any supplier from becoming a monopolist, meaning it is the only viable supplier for a particular good or service needed by the buyer. This would happen, for example, if all the supplier's competitors exited the market because of bankruptcy. A buyer facing a monopolist supplier cannot leverage competition. To avoid this fate, the buyer may award contracts to several suppliers to keep them solvent and thereby encourage their continued presence in future contract competitions.

In general, there are many considerations which might tip the scales in favor of one supplier or another, as evidenced by the long list of potential supplier evaluation dimensions provided in the section titled "Supplier Evaluation." The buyer might deliberately favor incumbent suppliers to foster trust and loyalty or, for example, to avoid the administrative costs of training a new supplier on the buyer's invoicing and payment procedures. Supplier location may also be a concern in a way not manifested in logistics costs. For instance, if the buyer's potential customers are governments, these customers may be more likely to purchase the buyer's products when the government's home suppliers benefit from the purchase. The buyer might also consider supplier diversity objectives when making award decisions. If the buyer organization has supplier diversity goals, preference is given to historically underrepresented or disadvantaged businesses, such as small businesses, minority- and women-owned

businesses, sheltered workshops and non-profit organizations, and so on. Supplier diversity is typically not legally mandated in private industry, and the amount of preference the buyer grants to underrepresented or disadvantaged businesses in any one supplier selection event is typically situation dependent. However, specifically mandated preferences may apply to government contracts [17].

Regardless of which award criteria are used by the buyer, making such criteria transparent makes it easier for the buyer organization to monitor its contract award decisions, to ensure the reasons for contract award are sound (e.g., due to the merits of the bid). For example, a "low price wins" rule makes it difficult for procurement managers to "cheat" the buyer organization by negotiating a sweetheart deal with a supplier in return for a bribe. For these and other reasons, the US government, for example, generally favors competitive negotiations for procurement, with clearly announced rules for determining the winner [17].

Supplier Monitoring

Many contracts specify the provision of goods over an extended duration of time, ranging from weeks to years. Monitoring supplier performance during the life of the contract has several aims. For example, it supports quality if the buyer inspects incoming goods to ensure that they conform to quality specifications. Monitoring also supports cost containment—if there is a problem with quality, it can be identified and charged back to supplier. For supplier selection itself, however, monitoring is most important in so far as it helps the buyer make more informed supplier selections in the future.

In particular, during supplier evaluation the buyer may consider factors that influence the total cost of doing business with the supplier. Such costs can include, for example, the conformance and nonconformance costs, which the buyer anticipates will be incurred during the life of the contract (e.g., costs of inspections and defect correction, respectively). These fall under the supplier evaluation dimension of "past performance" listed in the section titled

“Supplier Evaluation.”) The buyer may forecast these costs for each supplier—see Ref. 18 for examples of how this is done in practice. These forecasts can be constructed using historical performance data collected through supplier monitoring. For instance, the supplier’s historical percentage of defective items can inform the buyer’s forecast for nonconformance costs during the life of a contract. [If, on the other hand, the supplier is new and thus the buyer’s protocols require more careful inspection of incoming material (conformance costs), this also needs to be taken into account by the buyer at the time of supplier evaluation.] Historical information about supplier performance can also be leveraged during the negotiation process with suppliers. The buyer may choose to directly incorporate this information into a competitive bidding process via a bid markup or some other means to send a clear signal to the supplier about the importance of performance [18].

SUPPLIER SELECTION RESEARCH

Extant research on supplier selection can be divided into two broad streams. The first stream dominates the purchasing literature and identifies appropriate criteria and methods supporting supplier evaluation. The primary goals are to help the buyer decide what its objectives are, what the dimensions to evaluate suppliers over are, and how to evaluate suppliers using these dimensions. The second stream assumes that the buyer knows what it wants and has an existing methodology for evaluating suppliers. It focuses on decisions such as what types of negotiation formats or contracts to employ and how to elicit information that suppliers may be reluctant to reveal.

ORMS research on supplier selection typically falls into the second stream of research (although powerful OR tools such as math programming are also very useful in the first stream). This research typically employs parsimonious models of the supplier evaluation process, providing clear objectives for the suppliers and buyer. As such, these models often most closely align

with RFQ processes for the award of a well-specified contract, for which supplier evaluation issues are relatively transparent. Typically the perspective taken is that of a buyer seeking to award a contract to one or more competing suppliers possessing private information about their cost to fulfill the contract. The competitive negotiation process is often modeled as an auction or auction-like procedure—see the section titled “Game Theory: Extension and Development”. To ensure a consistent model of behavior, typically all actors (buyer and suppliers) are assumed to be fully rational—see the section titled “Non-Cooperative Extensive-Form (NCEF) Games of Perfect Information.”

For illustrative purposes, in the next section we provide examples of ORMS models applicable to supplier selection. We then conclude this section, and the article, with examples of supplier selection research topics that employ such ORMS models; see the section titled “Examples of ORMS Supplier Selection Research.”

Examples of Supplier Selection Models in ORMS

As mentioned above, ORMS supplier selection models often focus on RFQ settings. The typical setting studied is one in which it is relatively easy to evaluate supplier bids, but the supplier has private information about what contract terms (e.g., payment size) it would be willing to accept. For example, the buyer would like to find the lowest-cost supplier, and each supplier i knows its cost to perform the contract is x_i , while the buyer only has a prior belief that the cost follows some probability distribution F .

Auctions are common in practice and are also convenient for modeling. They are often invoked as a structured way to model the act of soliciting information (bids) from suppliers and negotiating contract terms. An auction is no more than a set of rules determining how suppliers will pass information to the buyer, and how the buyer will use this information in determining the contract award winner(s) and payment(s).

Once auction rules are combined with assumptions on the suppliers’ behavior, the model can be used to predict the contract

winner and payment. This perspective is quite useful for analyses, as it accommodates questions such as “how will different auction formats affect the contract winner and payments?” For example, suppose all bidders are fully rational. If the auction uses a second-price format, it is a dominant strategy for bidders to continue bidding down until they either win the auction or reach their true cost. This implies that for n suppliers the auction winner will be the bidder $j = \arg \min_{i=1,\dots,n} \{x_i\}$ and the expected contract price is $E[X_{2:n}]$, where $X_{2:n}$ is the second-lowest order statistic of n draws from distribution F .

Thus far we have discussed buyer beliefs, auctions rules, and supplier behavior, comprising the core ingredients of many ORMS supplier selection models. Additional embellishments to the core model can be added to address specific research questions. For illustrative purposes we will next briefly describe a model of supplier qualification screening.

With an auction model, an ORMS researcher can answer questions such as “what is the effect of an additional bidder on the expected contract payment?” Clearly, the expected contract payment decreases with the number of suppliers, raising the natural question of how many suppliers the buyer should invite to its auction. From the section titled “Identifying Potential Suppliers,” we know that identifying suitable suppliers is costly for the buyer. This motivates ORMS supplier selection models that incorporate costs associated with supplier qualification screening. Qualification screening can be thought of as a process whereby the buyer incurs a cost to learn information about the supplier’s qualification. The following model discussion is from Ref. 19, which to our knowledge is the first paper in the ORMS and economics literature to model supplier qualification screening.

The qualification screening model begins by parameterizing qualification requirements. To this end, define a continuum of qualification requirements, with 0 representing requirements that every supplier satisfies and 1 representing requirements that virtually no supplier satisfies. Let $q_0 \in [0, 1]$

be the scalar along this continuum that represents the buyer’s preaward requirements. For each supplier i , define its qualification level q_i as the maximum qualification threshold that supplier i can pass. Owing to opaque qualification requirements set by the buyer (as discussed in the section titled “Supplier Qualification Screening Process,” e.g., gaining rapport with the buyer’s internal customer), supplier i does not precisely know its true qualification level q_i , but the buyer and supplier share the common belief that q_i is distributed according to probability distribution H . This setup could model, for instance, a buyer deciding to outsource a portion of its production currently done in-house, facing new suppliers it knows little about and who in turn know little about the buyer’s (possibly idiosyncratic) qualification requirements. The strictness of the buyer’s preaward requirements is captured by $1 - H(q_0)$, which equals the probability that $q_i \geq q_0$.

Under this model, the buyer and each supplier responding to the RFQ are equally unsure of the supplier’s qualification until costly qualification verification is undertaken by the buyer. If $q_i \geq q_0$, the buyer’s qualification process on supplier i would reveal that supplier i is qualified. The cost the buyer would incur to do so is denoted by K , the total cost to the buyer of verifying that an individual supplier meets all requirements to be deemed qualified. For example, K may include the cost of purchasing and testing supplier products, travel to supplier facilities abroad, and so on. For simplicity, this model assumes that K is the same for all suppliers. This assumption is most appropriate when suppliers are similar, at least in terms of the cost drivers of qualification, such as distance from the buyer or number of units that the buyer must purchase to run a test sample.

On the other hand, if $q_i < q_0$, supplier i would be rejected during the buyer’s qualification process after failing to meet a requirement. In this latter case, what cost would the buyer incur? Assuming that the requirements are nested (passing a larger threshold implies passing a smaller threshold, but not vice versa), the cost strictly increases with q_i and approaches K as q_i approaches q_0 . One may assume that the cost is linear and

normalized such that a threshold of 0 costs 0 to verify, implying that weeding out an unqualified supplier i costs the buyer q_i/q_0K . This is without loss of generality, because any nonlinear and strictly increasing cost function of q_i over $[0, q_0]$ can be renormalized to be linear by redefining q_i and renormalizing the distribution H . This completes the supplier qualification screening model.

This section provided a glimpse of ORMS supplier selection research models. The next section provides examples of ORMS supplier selection research topics which could be explored with such models.

Examples of ORMS Supplier Selection Research

As the above discussion in the present article indicates, there are many complexities and trade-offs involved in supplier selection, providing many opportunities for ORMS research. The following lists just a few of the complex trade-offs that need to be understood by the buyer, illustrating the types of questions that can be addressed by ORMS research.

Timing of Supplier Qualification. A buyer will typically only contract with a supplier who has passed qualification screening, but to cast a wide net a buyer may choose to consider bids from suppliers who have not yet passed qualification screening. Delaying some or all supplier qualification screening until after bids have been tendered can save time and money wasted on qualifying suppliers who are unable to offer competitive pricing. Industrial (i.e., nongovernment) buyers generally do consider bids even if the supplier is not fully qualified already [4]. The optimal timing of supplier qualification screening processes and price negotiations is studied in Ref. 19.

Scope of Negotiations (RFPs). Future ORMS research can be expected to inform practitioners about how best to include evaluation criteria that are currently considered to be too complex or subjective. These criteria will, with more advanced research, be quantified and subject to analytical comparisons. In industry, efforts at total-cost modeling date back by decades [18]. One goal for supplier selection might be to refine the total-cost

or life-cycle-cost analysis, so that it is more readily useable during negotiations with suppliers. To this end, ORMS research has studied so-called multiattribute negotiation mechanisms (also called *multiattribute auctions*, [20,21] and expressive bidding mechanisms (see **Quantum Game Theory** on combinatorial auctions), and many supplier evaluation methodologies have been developed in the purchasing literature [16].

Negotiation Formats. There is a wide body of economics literature that seeks to determine which rules of negotiation (or which “mechanism”) will work well in which situation. Owing to many complexities and the variety of situations encountered in supplier selection, a natural opportunity exists to study which rules of negotiation work well in supplier selection. For example, the buyer’s preference between total-cost open-bid and sealed-bid auction formats can be driven by how dissimilar the suppliers are in terms of their nonprice factors such as historical conformance and nonconformance costs [22].

Supply base Design. When suppliers are concentrated in the same region, the buyer is vulnerable to cost risks such as spikes in transportation costs between the buyer’s location and the supplier region, for example, due to a strike at the port of origin. Choosing suppliers in different regions lessens the correlation between suppliers’ total costs, but this helps the buyer only if she is able to prevent windfall profit-taking by low-cost suppliers. Wan and Beil [23] studied the relationship between the buyer’s bargaining power (ability to prevent suppliers from taking windfall profits) and the optimal level of diversification of the supply base across regions.

Additional research topics include understanding supplier collusion and methods to mitigate its effects, and research refining the typical assumptions of ORMS supplier selection research (such as laboratory tests of bidder rationality in auctions).

The present article provides a very basic introduction to the goals, complexities, and terminology of supplier selection. Interested readers are encouraged to refer to the section titled “Further Reading” for articles that can

serve as a point of departure for further study into supplier selection.

SUPPLY CHAIN COORDINATION

FUQIANG ZHANG
Olin Business School, Washington
University, St. Louis, Missouri

A supply chain is a network of firms/entities that convert raw materials and components into final products and then deliver to consumers. If the supply chain is managed by a central planner who is able to control all decisions, then we call it a *centralized supply chain*. The set of actions that can optimize the supply chain's performance is called the *centralized optimal solution*. In practice, however, it is not uncommon for parties within a supply chain to be independent organizations that aim to maximize their own objectives. In this case, we call it a *decentralized supply chain*. The behavior of a decentralized supply chain can be characterized using the *Nash* or *Stackelberg equilibrium* concept (see ***Nash Equilibrium (Pure and Mixed)***).

Achieving *coordination* is equivalent to achieving the centralized optimal solution for the supply chain.¹ Under the centralized optimal solution, the pie for the entire system is maximized, so each player in the system can enjoy a larger size of the pie. This implies that under supply chain coordination, the players can achieve *Pareto optimal* profit allocations, that is, it is not possible to increase the profit of one player without hurting the profit of the other. Clearly, a coordinated supply chain is an ideal situation, since all players can be better off than without coordination. Unfortunately, since the players have different objectives and interests, the equilibrium outcome in a decentralized supply chain

often deviates from the centralized optimal solution, thus creating inefficiencies in the supply chain.

How to coordinate a decentralized supply chain is a central issue in supply chain management. One solution is to design a contractual scheme to align the incentives among all players so that the optimal actions coincide individually with the centralized optimal actions. In fact, many commonly observed contracts can serve as coordination devices. This article provides an introductory review on how to achieve the goal of supply chain coordination using such contractual arrangements.

A real-world supply chain could be extremely complex. For example, it may have an intricate network structure involving an arbitrary number of firms, each firm may have private information about its own cost and demand forecast, and the actions taken by firms may not be observable or verifiable. As an illustrational example, throughout this article, we consider a simple supply chain consisting of only two firms—a supplier and a retailer. The retailer is modeled as a newsvendor, that is, she faces a random demand in a single selling season and decides on the quantity to order from the supplier (see ***Newsvendor Models***). (We use “she” for the retailer and “he” for the supplier throughout this article.) Everything is common knowledge and there are no hidden actions. Also, all players are risk-neutral; so, they try to maximize their expected profits. We demonstrate how several commonly observed contracts can be used to coordinate this simple supply chain. We also provide intuitive explanation for the reason why these contracts can realign the incentives of the supply chain members. For a more comprehensive treatment of general supply chain coordination problems, readers are referred to Cachon [2].

This article is organized as follows. The section titled “Basic Model” introduces the basic model and the concept of *double marginalization* in a decentralized supply

¹This is a typical definition of supply chain coordination in the research literature. A more general definition is that all supply chain members take actions together to increase (not necessarily optimize) total supply chain performance. See Chopra and Meindl [1] for more details and practical examples.

chain. The section titled “Supply Chain Coordination Contracts” proposes several contracts to coordinate the supply chain. The section titled “Additional Issues” briefly discusses some additional issues in supply chain coordination. And, this article is concluded in the final section.

BASIC MODEL

Consider a supply chain consisting of a supplier and a retailer. The retailer sells a product in a single selling season at a fixed price p . Market demand D is random and has a distribution (density) function $F(f)$. The retailer procures the product from the supplier. The supplier incurs a cost c for each unit of product delivered to the retailer. Owing to long production and transportation lead times, the retailer has to decide on the order quantity before the market demand is realized.² In the case where the demand is less than the order quantity, leftover inventory at the end of the selling season has a unit salvage value $0 \leq v < c$. (Note that there are several additional parameters that we may add into the basic model. For instance, there could be a penalty cost for unsatisfied demand, the retailer may have to incur a unit cost as well for selling the product. However, the introduction of these parameters will not affect the understanding of the coordination contracts. So, we omit these parameters for ease of exposition.) For notational convenience, let E denotes the expectation operation and also, defines $x \wedge y = \min(x, y)$, $x^+ = \max(0, x)$, and $\bar{F} = 1 - F$.

²This supply chain setting (i.e., a supplier selling through a newsvendor retailer) is standard in the operations literature. In such a setting, the retailer faces a fixed retail price but uncertain market demand. Alternatively, we can model the retailer as a price-setting firm but with deterministic demand. The latter model setting has been widely used in studying channel coordination in the marketing literature. Although it is not the focus of this article, interested readers are referred to Jeuland and Shugan [3] and Moorthy [4] for more details on how to coordinate supply chains with deterministic market demand.

Centralized Optimal Solution

We first present the centralized optimal solution for the above supply chain. Latter we will use this solution as a benchmark for comparison. When the supplier and the retailer are controlled by a central planner, the retailer can obtain the product from the supplier at cost c . So, the supply chain’s problem reduces to the classic newsvendor problem. Observe that the supply chain’s profit is solely determined by the retailer’s order quantity. Let Q be the order quantity. Then the supply chain’s expected profit is given by

$$\begin{aligned}\pi_c(Q) &= pE(Q \wedge D) + vE(Q - D)^+ - cQ \\ &= (p - v)E(Q \wedge D) + (v - c)Q.\end{aligned}\quad (1)$$

We use subscript c for centralized supply chain. It is straightforward to show that $\pi_c(Q)$ is concave (i.e., $\pi_c''(Q) < 0$). Thus, the following first-order condition characterizes the profit-maximizing quantity Q_c^* for the centralized supply chain

$$\left. \frac{d\pi_c(Q)}{dQ} \right|_{Q=Q_c^*} = (p - v)\bar{F}(Q_c^*) + (v - c) = 0$$

or

$$F(Q_c^*) = \frac{p - c}{p - v}.\quad (2)$$

Equation (2) is the critical fractile solution to the classic newsvendor problem. Note that the centralized optimal solution Q_c^* increases in price p and salvage value v and decreases in cost c .

Wholesale Price Contract

Next, we consider the behavior of a decentralized supply chain. That is, now the supply chain members are independent entities that try to maximize their own objectives. We use a wholesale price contract to highlight how a decentralized supply chain may deviate from the centralized optimal solution. Under the wholesale price contract, the supplier charges a unit price $w > c$ for each unit of product delivered to the retailer. Assume that the wholesale price is exogenously given, that is, the wholesale price contract has already

been established at the outset. The sequence of events is as follows: The retailer places an order at the supplier; the supplier produces the product and delivers to the retailer; then market demand is realized and sales begin; finally, the selling season ends and leftover inventories are salvaged. Below we analyze the behavior of the supply chain under the wholesale price w .

The retailer's problem under the wholesale price arrangement is the same as in the centralized supply chain, except that the procurement cost is w rather than c . Given an order quantity Q , the retailer's expected profit now becomes

$$\begin{aligned}\pi_r(Q) &= pE(Q \wedge D) + vE(Q - D)^+ - wQ \\ &= (p - v)E(Q \wedge D) + (v - w)Q.\end{aligned}\quad (3)$$

We use subscript r for the retailer. Similarly, $\pi_r(Q)$ is concave and the first-order condition for the retailer's profit-maximizing order quantity Q_w^* is given by

$$F(Q_w^*) = \frac{p - w}{p - v}, \quad (4)$$

where the subscript w stands for wholesale price.

By comparing the Equations (2) and (4), we can see that $Q_w^* < Q_c^*$, since F is an increasing function and $w > c$. That is, under the wholesale price contract, the retailer tends to order less than under the

centralized optimal solution. Such a result can be explained using the standard risk analysis in the newsvendor problem. Since market demand is uncertain, the retailer essentially bets against demand when making an ordering decision. If demand realization is high, then the retailer loses $p - c$ potential profit for each unit of unmet demand. This is known as *underage cost* for a newsvendor. On the other hand, if demand realization is low, then the retailer incurs a loss of $c - v$ for each unit of leftover inventory. This is called *overage cost* for a newsvendor. It is quite intuitive that all else being equal, the retailer's optimal order quantity increases in the underage cost and decreases in the overage cost. Under the wholesale price contract, the underage cost decreases to $p - w$, while the overage cost increases to $w - v$, which leads to a lower order quantity at the retailer.

An alternative explanation of the above under-ordering result emerges from the marginal analysis (see Ref. 4 for the use of marginal analysis in channel coordination under deterministic demand). Under centralized control, the retailer's (i.e., the supply chain's) expected profit in Equation (1) can be divided into two parts: the revenue part, $pE(Q \wedge D) + vE(Q - D)^+$, and the cost part, cQ . The retailer's optimal order quantity is achieved at the point where the marginal revenue equals the marginal

Figure 1. Retailer's marginal revenue as a function of order quantity Q ($c = 3$, $p = 5$, $v = 2$, $w = 3.5$, D is normal with $N[100, 30^2]$).

Figure 2. Supply chain members' profits as functions of the wholesale price w ($c = 3, p = 5, v = 2, D$ is normal with $N[100, 30^2]$).

cost. Note that under the wholesale price contract, the retailer's revenue function in Equation (3) is the same as the supply chain's revenue function. This means that the retailer's marginal revenues are the same in both cases. However, the retailer's marginal cost increases from c (in the centralized supply chain) to w (in the wholesale price contract). Figure 1 uses a numerical example to visualize how the retailer's optimal order quantity is determined. In this example, $c = 3, p = 5, v = 2$, and the demand D follows a normal distribution with mean 100 and standard deviation 30. In a centralized supply chain, the retailer's optimal order quantity Q_c^* is determined by equalizing the marginal revenue and the marginal cost $c = 3$. Similarly, in a decentralized supply chain, the retailer's optimal order quantity Q_w^* is determined by equalizing the marginal revenue and the marginal cost $w = 3.5$. We can see that a higher marginal cost leads to a lower order quantity for the retailer (i.e., $w > c$ leads to $Q_w^* < Q_c^*$).

Since the supply chain profit depends on the retailer's order quantity, it means that the wholesale price contract does not maximize the supply chain's performance. This is the so-called *double marginalization* problem: The wholesale price exists because

the supplier requires a unit profit margin $w - c$ on top of that for the retailer, which in turn leads to a lower order quantity by the retailer and creates inefficiencies in the supply chain. Such an effect was first identified in Ref. 5. For the same numerical example described above, Fig. 2 shows the supplier's, the retailer's, and the supply chain's expected profits as functions of the wholesale price w . As we can see, the supply chain's profit curve declines as the wholesale price increases. That is, a more severe double marginalization problem leads to higher efficiency loss for the supply chain. The retailer's profit also decreases in the wholesale price, which is intuitive. The supplier's profit curve is slightly different. It increases first and then decreases in wholesale price. This is because while a higher wholesale price means a higher unit profit margin, it also forces the retailer to order less. So, the supplier's profit is not monotone in wholesale price.

The double marginalization problem implies that more sophisticated contractual arrangements (relative to the wholesale price contract) are needed to induce the retailer to order the centralized optimal solution. From the above marginal analysis, we essentially need to design a contractual scheme in which

the retailer's marginal revenue and marginal cost curves intercept at the supply chain's optimal solution, Q_c^* . We show in the next section how to achieve this goal via carefully designed contractual arrangements.

SUPPLY CHAIN COORDINATION CONTRACTS

The above analysis has shown that the wholesale price contract induces the retailer to order less than the supply chain optimal quantity. We need to increase the retailer's order quantity in order to achieve coordination. In this section, we show that several commonly observed contracts in practice can achieve coordination by manipulating the retailer's marginal revenue and/or marginal cost curves. To save space, we focus on the following three contract formats: buyback, quantity discount, and revenue-sharing contracts.

Buyback Contract

A buyback contract contains two parameters (w, b) . The retailer pays a wholesale price w to the supplier; at the same time, the supplier agrees to buy back the leftover inventories at a buyback price b ($v < b < c$). (If $b \leq v$, then the buyback is useless because the retailer is better off salvaging the leftover inventories by herself; if $b \geq c$, then the retailer will order infinity.) This is also known as *return policies*. For example, in the book industry, many publishers offer buyback terms to retailers, that is, unsold books can be returned to the publisher at the end of the selling season for a certain price. Notice that the supplier does not have to physically take the products back in a buyback contract; rather, he only needs to subsidize the disposed excess stock. Pasternack [6] was among the first to study buyback contracts in the context of the newsvendor problem. Intuitively, buyback price b improves the retailer's marginal revenue from salvaging the leftover products (i.e., from v to b) and thus should increase her order quantity, and a large enough b should bring the retailer's order quantity back to the centralized optimal solution. (Equivalently, we may use the underage and overage cost

concepts to explain why buyback contracts work. In particular, the buyback policy can induce the retailer to order more because it reduces the retailer's overage cost from $c - v$ to $c - b$.) Next, we confirm this conjecture.

Under the buyback contract, the retailer's expected profit can be written as

$$\begin{aligned}\pi_r(Q) &= pE(Q \wedge D) + bE(Q - D)^+ - wQ \\ &= (p - b)E(Q \wedge D) + (b - w)Q,\end{aligned}\quad (5)$$

which is concave in Q . Through manipulation, we can derive the first-order condition for the retailer's profit-maximizing order quantity, Q_b^*

$$\left. \frac{d\pi_r(Q)}{dQ} \right|_{Q=Q_b^*} = (p - b)\bar{F}(Q_b^*) + (b - w) = 0,$$

which gives

$$F(Q_b^*) = \frac{p - w}{p - b}. \quad (6)$$

We use subscript b for buyback. To coordinate the supply chain, we need $Q_b^* = Q_c^*$, or

$$\frac{p - w}{p - b} = \frac{p - c}{p - v} \quad (7)$$

by comparing Equations (2) and (6). Thus, any combination of values for (w, b) that satisfy Equation (7) can coordinate the supply chain. Note that there are an infinite number of solutions to Equation (7). Now the question is: Which one should we use to coordinate the supply chain? It turns out that different solutions of (w, b) correspond to different profit allocations between the supplier and the retailer. To see this, let

$$w = p - \phi(p - c) \text{ and } b = p - \phi(p - v), \quad (8)$$

where $0 \leq \phi \leq 1$ is a constant. It is easy to verify that Equation (7) holds, so the pair (w, b) given in Equation (8) coordinates the supply chain. Further, the retailer's expected profit in Equation (5) can now be written as

$$\begin{aligned}\pi_r(Q) &= \phi(p - v)E(Q \wedge D) + \phi(v - c)Q \\ &= \phi\pi_c(Q).\end{aligned}\quad (9)$$

That is, the buyback contract in Equation (8) not only coordinates the supply chain, but also assigns a portion ϕ ($0 \leq \phi \leq 1$) of the supply chain profit to the retailer (the supplier gets a portion of $1 - \phi$). The ability to achieve arbitrary allocation of profits between supply chain members is a desirable property. In many cases, the supply chain members have unequal bargaining powers and as a result, they may require different profit allocations in order to participate in coordination. From the above analysis, it is clear that buyback contracts can serve both purposes well (i.e., coordination and arbitrary profit allocation). It follows from Equation (8) that a lower ϕ corresponds to a higher b , which implies that a higher buyback price leads to a lower retailer profit. This is mainly because a higher buyback price is associated with a higher wholesale price w .

Finally, there are some variations of the buyback contract in practice. For instance, it is common that fashion manufacturers use the so-called *markdown money* to compensate the retailers for liquidated items via clearance pricing. In a markdown money contract, the markdown money can be a percentage of the price markdown, or it can be a rebate credit for each unit of salvaged product. Both forms of the markdown money have the same effect on the retailer's decision as the buyback term in the buyback contract. Another related example is quantity flexibility (or backup agreement). In a quantity flexibility contract, similarly, the supplier charges a wholesale price but subsidizes the retailer for unsold units. To be specific, the supplier is fully responsible for a portion of the retailer's order (note that the supplier provides partial protection on the retailer's entire order in the buyback contract). See Refs 7 and 8 for more discussion of quantity flexibility contracts.

Quantity Discount Contract

The buyback contract coordinates supply chains by altering the retailer's marginal revenue curve. Similarly, to achieve coordination, we may manipulate the retailer's marginal cost curve so that it crosses the marginal revenue curve precisely at Q_c^* , the order quantity that is optimal for the supply

chain. Consider the following so-called *quantity discount* contract: The supplier charges the retailer a unit wholesale price $w(Q)$, which is a function of the order quantity Q . This is also called an *all-unit* quantity discount, because the wholesale price applies to the entire order quantity. By definition of the quantity discount, we focus on $w'(Q) < 0$, that is, wholesale price functions that are decreasing in order quantity. This type of arrangement is quite common in practice, where a buyer enjoys a lower price by buying more (e.g., many consumer packaged goods suppliers routinely offer incentives to induce large order quantities from their retailers). Next, we analyze this quantity discount contract.

Under this contract, the retailer's expected profit is given by

$$\begin{aligned}\pi_r(Q) &= pE(Q \wedge D) + vE(Q - D)^+ - w(Q)Q \\ &= (p - v)E(Q \wedge D) + (v - w(Q))Q.\end{aligned}\quad (10)$$

Similar to the analysis of buyback contracts in the section titled "Buyback Contract," we try to express the retailer's profit function $\pi_r(Q)$ as a fraction of the supply chain's profit. Let

$$\begin{aligned}w(Q) &= (1 - \phi)(p - v) \left(\frac{E(Q \wedge D)}{Q} \right) \\ &\quad + \phi(c - v) + v,\end{aligned}\quad (11)$$

where $0 \leq \phi \leq 1$ is a constant. Plugging the above $w(Q)$ into Equation (10) gives

$$\begin{aligned}\pi_r(Q) &= \phi(p - v)E(Q \wedge D) + \phi(v - c)Q \\ &= \phi\pi_c(Q).\end{aligned}\quad (12)$$

Hence, under the quantity discount scheme in Equation (11), the retailer's incentive is aligned with the supply chain's because $\pi_r(Q) = \phi\pi_c(Q)$. The retailer keeps ϕ ($0 \leq \phi \leq 1$) portion of the supply chain profit.

Since

$$\begin{aligned} \frac{d\left(\frac{E(Q \wedge D)}{Q}\right)}{dQ} &= \frac{\bar{F}(Q)Q - E(Q \wedge D)}{Q^2} \\ &= -\frac{\int_0^Q xf(x)dx}{Q^2} < 0, \end{aligned}$$

we know $w(Q)$ is a decreasing function of Q , that is, $w(Q)$ represents a quantity discount scheme. Note that $w(Q) \rightarrow \phi(c - v) + v \leq c$ as $Q \rightarrow \infty$, which means that the wholesale price the supplier charges could be lower than the cost c . However, this will never be the retailer's optimal choice because the supplier's, and therefore all parties' profits are negative when the order quantity is excessively large.

From the given Equation (12), we know that any order quantity that maximizes the retailer's profit will also maximize the supply chain's profit. Essentially, it implies that, by using a properly designed quantity discount contract, we can achieve supply chain coordination and arbitrarily allocate profits between the supply chain members.

Revenue-Sharing Contract

So far we have introduced two coordination contracts: buyback contracts and quantity discount contracts. In buyback contracts, a buyback term is used to improve the retailer's marginal revenue curve and thus induce the retailer to take the supply chain optimal action. In quantity discount contracts, a nonlinear wholesale price function is used to manipulate the retailer's marginal cost curve so that it intersects with the marginal revenue curve at the supply chain optimal quantity. What happens if we use certain contractual schemes to adjust both the marginal revenue and marginal cost curves? In this section, we study revenue-sharing contracts that can achieve supply chain coordination by manipulating both the retailer's marginal revenue and marginal cost curves. The practice of revenue-sharing has been observed; for instance, in the video rental industry, where studios offer movie copies to rental stores at relatively cheap prices, and

as a compensation, the rental stores agree to share revenue with the studios.

Let $\{w, \lambda\}$ denote a revenue-sharing contract, where w is the wholesale price and λ is the revenue share (i.e., the portion of the supply chain's expected revenue) obtained by the retailer. To be more specific, the retailer pays the supplier w for each unit of product, and meanwhile, the retailer keeps λ portion of the revenue from either selling or salvaging each unit of product. Under revenue sharing, the retailer's expected profit is given by

$$\begin{aligned} \pi_r(Q) &= \lambda[pE(Q \wedge D) + vE(Q - D)^+] - wQ \\ &= \lambda(p - v)E(Q \wedge D) + (\lambda v - w)Q. \end{aligned} \quad (13)$$

Consider the following parameters values for the revenue-sharing contract:

$$w = \phi c \text{ and } \lambda = \phi, \quad (14)$$

where $0 \leq \phi \leq 1$ is a constant. Then the retailer's profit becomes

$$\begin{aligned} \pi_r(Q) &= \phi(p - v)E(Q \wedge D) + \phi(v - c)Q \\ &= \phi\pi_c(Q). \end{aligned} \quad (15)$$

Thus, the revenue-sharing scheme in Equation (14) achieves coordination and assigns a portion of ϕ ($0 \leq \phi \leq 1$) profits to the retailer. Note that in a coordinating revenue-sharing contract, there is $w = \phi c \leq c$, which implies that the supplier should charge a wholesale price that is not greater than his cost. Therefore, instead of charging a markup when selling to the retailer, the supplier makes profits solely from sharing the revenue with the retailer.

It is worth mentioning that we may go one step further to coordinate a supply chain via profit sharing. That is, both firms agree to take actions to maximize the supply chain's objective, and then split the total profits between themselves. Another related coordination device is the so-called *two-part tariff* contract. In this type of contract, the supplier delegates all decisions to the retailer (i.e., the retailer serves as a central planner for the entire supply chain), and in return,

the retailer compensates the supplier using a lump-sum payment. Both the profit-sharing and the two-part tariff notions are essentially equivalent to vertical integration, where supply chain firms merge into one. Although intuitive, it may not always be appropriate to propose the use of vertical integration as a coordination solution. In fact, there could be numerous factors that may prevent firms from easily integrating with each other in a supply chain (e.g., firms would like to gain control of their own decisions, there may be additional administration costs due to more complex organizational structure, and different firms may be endowed with different amounts of information, etc.). More discussion of the comparison between revenue-sharing and other coordination contracts can be found in Cachon and Lariviere [9].

ADDITIONAL ISSUES

The previous section proposes three different supply chain coordination contracts (i.e., buyback, quantity discount, and revenue-sharing). All three contracts are able to induce supply chain optimal actions and allocate profits between firms in a flexible way. Although they seem to work equally well, they have different implications in practice. In particular, some contracts might be relatively easier to implement than others under different situations. A detailed discussion of the advantages and the disadvantages of the coordination contracts is beyond the scope of this short article. Moreover, we have illustrated the three contracts using the simplest supply chain setting. The most practical situations are much more complex than the one described in the previous sections. As a result, the above three contracts may or may not be able to coordinate these more complex supply chains. In this section, we briefly explain the additional issues that may complicate our supply chain coordination analysis. The purpose is to provide a preliminary introduction of more realistic problem settings, but not to give a thorough solution to these new coordination problems. Nevertheless, we list the representative references that address these additional issues.

Multiple Periods

The basic model in the section titled “Basic Model” considers a single-period problem in which the retailer makes an ordering decision only once. The single-period model is appropriate for perishable products that have short life-cycles (e.g., books, fashion items, high-tech products). For products with longer life spans, a multiperiod model might be more reasonable. In this case, the retailer can regularly replenish inventory from the supplier, and the supply chain may become a two-echelon inventory system (when the supplier makes to stock) or a production-inventory system (when the supplier makes to order). Cachon and Zipkin [10] and Caldentey and Wein [11] study how to coordinate these two different systems, respectively.

Multiple Retailer Decisions

There is a single decision in the basic model, that is, the retailer’s order quantity. Coordination is relatively easy because one only needs to make sure the retailer adopts the supply chain’s optimal order quantity. However, in practice, there are many situations where the retailer needs to make more than one decision. One of the common decisions made by a retailer is sales effort. Imagine that a retail store influences demand by using promotional displays, offering shopping assistance, and giving out gift cards and coupons. Taylor [12] and Krishnan *et al.* [13] study how to coordinate a supply chain in which the retailer makes both ordering and sales effort decisions. In particular, they investigate the so-called *sales rebate* contract where the supplier charges a wholesale price and at the same time compensates the retailer with a rebate for each unit sold beyond a certain target sales level. Another decision a retailer often makes is the retail price. How to coordinate a price-setting newsvendor? It turns out that the buyback contract does not work in this case in general. However, it can be shown that the revenue-sharing contract can still coordinate such a supply chain (see Ref. 9 for details).

Other Supply Chain Structures

A real-world supply chain may consist of a number of connected firms with various network structures. From a research point of view, we need to first understand the following three building-block structures: serial, assembly, and distribution supply chains. In a serial supply chain, there is only a single firm at each stage. The basic model studied in the section titled “Basic Model” is a typical example. An assembly supply chain consists of one manufacturer at the downstream stage, but there could be multiple suppliers at the upstream stage. The manufacturer uses the complementary components delivered by the suppliers to assemble a final product. To coordinate such an assembly system, one needs to consider both the vertical relationship (between the suppliers and the manufacturer) and also the horizontal relationship (between the suppliers). Bernstein and DeCroix [14] and Zhang [15] study the assembly inventory systems under periodic review and propose coordination schemes accordingly. Distribution supply chains are also commonly seen in practice. For example, a supplier sells his product through multiple independent retailers. Recent research that addresses the coordination problem for distribution supply chains can be found in Chen *et al.* [16], Bernstein and Federgruen [17], Narayanan *et al.* [18], and Krishnan and Winter [19].

Asymmetric Information

When supply chain members are independent organizations, it is natural that they are endowed with different types and amounts of information about the supply chain. For example, the supplier may possess private information about production cost, while the retailer may have superior information about market demand. Two types of asymmetric information have been widely investigated in the supply chain management literature: cost and demand information. When asymmetric information is present, supply chain coordination is not always achievable. This is because supply chain coordination requires information sharing among the supply chain firms, but truthful information sharing may

not be in the interest of the information holders. Chen [20] provides a review of the information-sharing literature in supply chain management (see *Information Sharing in Supply Chains*).

Strategic Customer Behavior

The traditional supply chain management literature models customer demand at an aggregate level and do not consider forward-looking customer behavior. This is clearly a simplification because demand is composed of individual consumers who may consciously react to market conditions. In the above basic model, there is a selling price p in the regular selling season, and then there is a salvage price $v < p$ in the markdown season. If a consumer anticipates a lower price after the regular season, this may affect her purchasing decision in the regular season. Specifically, if she waits, she may get the same product at a lower price, but she has to face the risk of a stockout after the regular selling season. How does this kind of consumer behavior affect supply chain management, and in particular, supply chain coordination? A recent research development is to explicitly incorporate the consumer side into the picture. Su and Zhang [21] study the impact of such strategic customer behavior on supply chain performance. Interestingly, they demonstrate that under the presence of strategic consumer behavior, a decentralized supply chain with a wholesale price contract can perform strictly better than a centralized supply chain. The reason is that a wholesale price (and thus double marginalization) actually helps the retailer to credibly commit to a low order quantity, which in turn induces the consumers to be willing to pay a high price in the regular season. This implies that the centralized optimal solution is not always the best benchmark for evaluating supply chain performance. Under strategic customer behavior, such a benchmark can be surpassed.

CONCLUSIONS

A decentralized supply chain consists of independent firms that wish to maximize their own objectives. As a result, the firms’ actions

often deviate from the actions that optimize the supply chain's performance. This article provides an introductory review on how firms can use various contractual schemes to achieve supply chain coordination. Three commonly observed contracts have been analyzed: buyback, quantity discount, and revenue-sharing. It has been shown that for a simple, two-stage supply chain, all these contracts can realign the firms' incentives to induce supply chain optimal actions. In addition, by properly choosing the contract parameters, we can achieve arbitrary profit allocations among supply chain firms.

For illustrational purpose, in this article we focus on a simple supply chain setting. Additional issues that complicate the coordination analysis may exist. We also provide a brief discussion of these issues. Some of the issues have already been addressed in the supply chain management literature, but some of them deserve further research attention. For example, the topic of information sharing has not been fully explored. Also, strategic customer behavior opens a new and promising research arena in supply chain management. Finally, there has recently been a fast-growing interest in studying the effect of supply uncertainties on firms' sourcing decisions. How to coordinate a supply chain with unreliable supply is an interesting topic for future research, too.

SUPPLY CHAIN OUTSOURCING

ANDY A. TSAY

OMIS Department, Leavey School of
Business, Santa Clara University,
Santa Clara, California

This article focuses on the outsourcing of manufacturing/production/assembly, procurement/sourcing, logistics, and product design/development. The first three in the list are traditionally considered to be the major supply chain functions, to which we add the fourth to acknowledge that design decisions strongly preordain the supply base and the manufacturing processes. Also, in modern practice, the insource-versus-outsource decisions for design and manufacturing are often intertwined. Alternatively this scope can be viewed as the endeavor of stewarding a product from concept to market, and then operating the resulting supply chain.

Since the outsourcing of a supply chain activity is a special instance of business process outsourcing (BPO), readers should first review the BPO article in this encyclopedia (see ***Business Process Outsourcing***). Similar to that entry, this article is intended to serve as a tutorial, and will not provide a comprehensive review of the research literature. The BPO article ends with a high-level assessment of extant operations research and management science (ORMS) research on general outsourcing that applies to supply chain outsourcing research as well.

We will discuss the outsourcing of each of the stated activities, with the caveat that they do not segment cleanly into distinct and sequential steps. Because of cross-functional coordination issues, the resolution of the insource-versus-outsource quandary for each activity depends on how the others are conducted. Further, the service providers are increasingly blending these into a package deal for their customers.

Supply chain outsourcing is of tremendous interest in the business community. While

the potential benefits are alluring, the magnitude of the risks is illustrated by recent high-profile crises faced by Cisco [1], Boeing [2], Mattel [3], and Menu Foods [4]. Most of those included offshoring as well, but the problems could be attributed primarily to the incentive conflicts and loss of visibility symptomatic of delegation to external providers of services.

OUTSOURCING OF MANUFACTURING

For many, outsourcing in the supply chain setting first brings to mind the treatment of manufacturing/production/assembly. The most basic form is the purchase of a standard material from an outside party, for which the proper control processes are generally well-understood and efficient. The need for managerial concern grows when the buyer obtains more complex manufacturing services from a service provider, such as when a brand owner engages a contract manufacturer to produce a noncommodity product using nonstandard processes.

The following terms are used by practitioners to characterize the key players in such settings:

OEM: original equipment manufacturer

OBM: original (or own) brand manufacturer

CM: contract manufacturer

The acronym OEM has classically referred to a party that makes and sells a branded product, but (somewhat anachronistically) continues to be applied to the brand owner even if the “M” is performed by another party. However, such a firm may decide “to OEM” a component, which means that the procured part will retain the supplier’s brand identity. In this usage, the term *OEM* refers to the supplier. Emerging from the electronics industry around 2004 [5], the OBM label is used to affirm that the brand owner is also performing the manufacturing. A CM manufactures products that ultimately

bear another party's brand, and traditionally does not own the intellectual property of the design.

This article will frame outsourcing's consequences from the OEM's perspective, since the OEM controls the decision of whether to outsource in the first place. Supply chain outsourcing inherits the motives for general outsourcing (see *Business Process Outsourcing*), but here the OEM's highest priorities are typically to avoid ownership of the factory workforce, assets and infrastructure, and to tap into specialized expertise that can quickly ramp to a cost-efficient and robust stream of supply. The increasing availability of a competent CM segment serving virtually every product category makes this possible. This is a boon to start-ups which may lack the capital for funding internal production (or elements of design, logistics, etc.). The lowering of these entry barriers has profoundly affected the competitive dynamics in many industries.

The general risks also persist, especially for the sourcing of complex or nonstandard manufacturing services rather than manufactured product. Context-specific concerns include the CM's counterfeiting the product, stealing proprietary processes, or simply not following the expected procedures. Even without deliberate malfeasance, coordination problems arise from inserting company boundaries between manufacturing and other key OEM functions such as product design or sales/marketing.

The coordination between design and manufacturing that is required to generate manufacturable designs (i.e., design for manufacturability, DFM; see *Design for Manufacturing and Assembly*) and accurate bills-of-materials is already elusive when the two functions are under the same roof. Separating into different companies only adds additional obstacles, such as incompatibilities in data formats, materials nomenclature, or part-numbering conventions.

OEM sales and marketing managers can struggle to monitor quality and manufacturing status when the manufacturing has been outsourced, particularly when products are spread across multiple CMs. These managers face frustrations trying to respond

to end-customer questions like "Where is my order and when will it ship?" or "Can I still change the configuration?" [6].

These points make apparent that the performance of any outsourcing strategy will depend on the needs for flow of information along partners in the resulting extended enterprise. This underlies the argument that product architecture drives supply chain architecture. A "modular" architecture includes a one-to-one mapping from functional elements to components, and specifies decoupled interfaces between components. An "integral" architecture includes a complex (non-one-to-one) mapping from functional elements to components and/or coupled interfaces between components [7]. Because decomposability reduces the need for communication, the writing of detailed specifications, and iteration in designing the parts for which each party is responsible, modular products (e.g., personal computers) tend to be built (and designed) by modular supply chains (heavy outsourcing; many suppliers for each component) while integral products (e.g., high-performance automobiles) tend to come from integral supply chains (little outsourcing; vertically integrated industry) [8]. In short, the supply chains can be "mix and match" only to the extent that the product components (and the associated business processes and IT platforms) are "plug and play."

A vast body of practitioner literature weighs in on the insource-versus-outsource question for manufacturing, and provides operational advice on engaging a CM. A recurring topic therein is the hidden costs of coordination. The need for cross-functional integration between design and manufacturing calls for CM involvement very early in the OEM's product design timeline, or even outsourcing design and manufacturing as a bundle to qualified CMs [9]. The consequences of the latter approach will be discussed in the section titled "Outsourcing of Product Design/Development." Information technology, in areas such as enterprise resource planning (ERP) or product life-cycle management (PLM), can also enhance the coordination across chasms created by outsourcing. Of course, technical connectivity can provide only limited benefit without compatible

data formats and business processes. These are the goals of standards such as the Partner-Interface-Protocol (PIPs) framework of RosettaNet (www.rosettanet.org) or the programs of the Voluntary Inter-Industry Commerce Solutions (VICS) consortium (www.vics.org) that include collaborative planning, forecasting, and replenishment (CPFR). These require a willingness to share information with partners and, to reiterate a recurring theme, nontrivial investments of human and financial resources.

For these reasons and others, insourcing of manufacturing remains a legitimate strategy. OEMs in various industries have affirmed their commitment to this approach [10,11].

OUTSOURCING OF PRODUCT DESIGN/DEVELOPMENT

While typically not as asset-intensive as manufacturing, maintaining superior product design capability can also be imposingly expensive, especially in the specialized human capital. The coordination difficulties noted earlier may also motivate the outsourcing of design in a way that reintegrates it with outsourced manufacturing activities. [Although theoretically possible, there is no evidence that any OEMs are outsourcing significant amounts of design while retaining manufacturing in-house [9].] Consequently, design outsourcing is a growing trend in many industries [12].

The term *design* can be applied to a vast range of activities, from generation of product concepts all the way to the creation of very precise schematics of product configuration. These pieces can be further subdivided, and any of the segments are candidates for outsourcing. Some firms even outsource the pursuit of breakthrough innovation (R&D) to specific organizations or to the open community. This could be broadened to consider innovation in processes or business models, not just designs of specific products. To invoke a recurring theme, design outsourcing is not a binary decision. Of course, a firm should be incessantly wary about outsourcing design activities that might fall among its core

competences. Indeed, in early 2009, amidst a broad economic crisis that had many of its rivals conducting massive layoffs, Apple Inc. was aggressively hiring specialized chip designers to work on key technologies. This reflected Apple's desire to get critical new features to market quickly while sharing fewer details about its technology plans with external chip suppliers [13].

Design outsourcing faces the challenges of services procurement explained in the article on BPO (see ***Business Process Outsourcing***). Communication and coordination across-company boundaries are particularly difficult because even though design can be performed much more systematically than most people think, it is still inherently a creative activity that entails working with ideas that are not fully developed, with many interdependencies among decisions. Further, the staff asked to liaison with the design service providers often, at least initially, lack the appropriate background and organizational support for the increased emphasis on project and relationship management [12,14].

Yet the stakes are high, especially for the many design decisions that have implications for manufacturing and supply chain management [9]. Among other impacts, design decisions strongly constrain the choice of materials, suppliers, and manufacturing processes. The folk wisdom is that roughly 70% or more of a product's life-cycle costs (manufacturing, supply chain, quality) are preordained at the design stage. (That design decisions are important is not in dispute, but the concrete evidence for this numeric rule of thumb is apocryphal. As Barton *et al.* [15] note, "Where authors support it by reference to published work, the references are to authors who themselves provide no substantive proof to support their claims. These referenced authors assert it themselves or quote a study by, or give a quote from, a major corporation. Examples of such corporations are Boeing, British Aerospace, General Electric, Rolls-Royce, Westinghouse, and Ford. With the exception of Rolls-Royce, the studies reportedly carried out by these major corporations cannot be easily traced as they are inadequately referenced, for example, as '...a Boeing

Figure 1. Smile Curve (Source: Version from <http://www.madeintaiwan.tv/blog/?p=10>).

study of turbine engines...’ or ‘...according to General Motors’ executives...’. Regarding Rolls-Royce, Barton *et al.* [15] emphasize that the widely quoted original study [16] actually concludes that good design decisions can reduce 80% of “unnecessary” costs rather than of total costs.)

In principle, one way to maximize the coordination between design and manufacturing decisions in an outsourced supply chain is to entrust both activities to the same service provider. The following two paradigms for such joint outsourcing have arisen in a variety of industries:

- CDM: contract (or custom or collaborative) design and manufacturing
 ODM: original (or own) design manufacturing (er)

The primary difference between CDM and ODM is in the ownership of the intellectual property (IP) in the product design. In the CDM model, the IP fully belongs to the OEM, whereas an ODM owns the product IP and is entitled to use it to create its own brands, products for other OEMs, generics, or white-box products. Additionally, ODMs take on inventory liability, while in the CDM model, the OEM generally owns the inventory. In these senses, a CDM is primarily a service company whereas an ODM is primarily a product company.

The historical evolution of both CDM and ODM reflect the reality that, in many industries and for many product types, manufacturing excellence has become a commodity. This is the notion that underlies the “(Stan

Shih) Smile Curve,” attributed to the founder of Acer who proposed it in 1992 [17]. One version of the framework appears in Fig. 1.

The Smile Curve originally addressed what semiconductor and electronic CMs (mostly Taiwan-based) experienced in the 1990’s, a phenomenon which persists in many industries today: the lion’s share of the wealth in the value chain seems to gravitate to the activities upstream and downstream of the manufacturing segment, so that the profitability of a traditional CM will be squeezed from both sides. This contributes another entry to the previous section’s list of OEM motives for outsourcing manufacturing, but here it conveys why the pure-play CM business model, even with its focus, economies of scale, and risk-pooling, seems so often to be a transient form on the way to either CDM or ODM.

Indeed, some traditional CMs have added CDM or ODM services in search of a sustainable means of differentiation, one able to command higher margins. CMs are thus able to enhance their manufacturing competitiveness by generating designs that are efficiently manufacturable.

CDM is less dramatic a transformation for a CM, so the documentation of this phenomenon seems to focus more on the ODM form. The majority of written coverage of ODM has been in the press surrounding the electronics industry. There the ODMs grew out of the motherboard companies in Taiwan, who moved into computer systems, especially notebook computers. A resulting misconception is that this organizational

format is unique to electronics. In fact, the model appeared earlier in bicycle manufacturing and possibly elsewhere. Apparel ODMs reside in various parts of Asia, especially Hong Kong and Korea.

OEMs are increasing their usage of both models. This suggests that the motives for manufacturing outsourcing are compelling, but that design and manufacturing need to go together. Beyond that the OEM still must choose a specific model, neither of which dominates the other.

An OEM benefits from the turnkey aspect of either solution, as CDM and ODM service providers both allow an OEM to tap into a supply chain possessing many of the benefits of vertical integration. An ODM provides a virtually complete product off-the-shelf to fill out an OEM's product portfolio, a fast solution that allows the OEM to reduce in-house R&D expense but with only limited customizability. However, the ODM needs to supply multiple OEMs to recover the cost of R&D for a platform and to mitigate the inventory risk. As noted, ownership of the IP entitles the ODM to supply the OEM's direct competitors, as well as to become a competitor itself via white-box or own-brand products.

This raises the ultimate question for the OEM, which is how to differentiate its brand when its ODM-supplied product is technically equivalent to many others on the market. ODMs are very protective of the identities of their clients for this reason, lest end-consumers start to view their products as a commodity. For mobile computers, a category which is predominantly supplied by Asian ODMs, OEMs such as Hewlett-Packard pursue differentiation through the industrial design of the chassis, the software bundle, and after-sale support.

ODMs have both the motivation (as indicated by the Smile Curve) and the prerogative to become OBMs. Indeed, the evolutionary path from CM to ODM to OBM is well-documented for firms in late-industrializing economies such as Taiwan, Korea, Singapore, and Malaysia [18,19]. Firms that started as CMs offering cheap labor learned design skills and market insights from sophisticated customers who needed to transfer this knowledge to preserve

DFM. Eventually these ODMs aspired to develop their own brands to increase their control and financial returns.

If an OEM does not design or manufacture, what competitive capabilities does it retain that are so hard for ODMs to learn or obtain? Earlier, the Taiwanese electronics ODMs had only limited success achieving sustained global brand awareness, forcing them to compete on price. Challenges include the need to develop sophisticated distribution channels with infrastructure for functions such as handling returns, offering credit, and providing warranty service, and the marketing expertise that provides the deep customer knowledge critical to the conception of attractive products. However in some cases, a CM or ODM can obtain these rapidly through an acquisition. In any event, an OEM outsourcing design to its manufacturing partner should proceed under the assumption that this partner will eventually become a direct competitor.

OUTSOURCING OF PROCUREMENT

Procurement already implies outsourcing, in that some good or service is being purchased from outside a firm. The buying firm has another outsourcing decision to make beyond that, regarding whether management of the procurement activity itself should also be entrusted to an outside party.

The outside party can be a focused procurement specialist, to which some apply the label "procurement service provider" (PSP). These offer not only capacity and expertise, but also assets such as supplier databases and technology for conducting reverse auctions.

Alternatively, the magnitude of the financial impact may present a valid business case for integrating the manufacturing and direct materials decisions. This approach can prevent myopic actions such as choosing the cheaper component in ignorance of the detrimental impact on assembly cost. "Turnkey" engagement of a CM, in which the CM is entirely responsible for providing the end product to the OEM, ostensibly produces tight integration with the least overhead

while retaining the benefits of manufacturing outsourcing.

CMs have financial incentives to take over the OEM's procurement of direct materials, for which they typically earn a percentage markup over the cost of materials. In addition, because financial analysts sometimes base certain metrics on revenue, the ability to count the flow of materials as revenue can elevate a CM's public stature. In the electronics sector, for example, materials can represent 75–80% of a CM's revenue. At the same time, competition has pressured the margins that CMs can earn solely by manufacturing. Some CMs now view direct manufacturing as a loss leader for driving business through the profit center that direct procurement has become.

A strategic view of procurement understands that control of the buying decision is a precious asset. The livelihood of any seller depends on making buyers happy, and sophisticated or large-scale buyers may be able to extract strategically significant treatment from suppliers. This preferential treatment can take the form of low prices (either straightforwardly or indirectly through rebates and other subsidies), short lead times, liberal return privileges, forgiveness of occasional contract noncompliance, assurance of supply in times of scarcity, influence over technology road-maps, technical support, and so forth. Thus, something more profound than markup on materials changes hands when an OEM outsources procurement; the OEM may cede control of the preferential treatment as well.

OEMs have a variety of options for retaining control of procurement while still outsourcing manufacturing. Between turnkey outsourcing, which exposes the OEM to a long list of hazards, and full insourcing of procurement, in which the OEM foregoes the potential benefits of outsourcing, are a number of procurement models that seek a compromise by incorporating various preventive and reactive business controls. Amaral *et al.* [20] summarizes the strengths and weaknesses of a number of such approaches:

In-House

With in-house procurement, OEMs buy directly from suppliers, managing storage

and transit to CMs. In electronics, OEMs began with this approach when they first outsourced production by providing prepackaged part kits to CMs for overflow assembly work. The OEM completely controls procurement in this way, which minimizes outsourcing risks.

Such control is costly. In-house procurement requires fully staffed organizations, highly integrated information systems, and distributed sites for planning, executing, and managing the inbound supply chain from suppliers to CMs. OEMs must stay abreast of technical developments and in contact with potential suppliers around the world. They must also maintain inventory storage locations (hubs) near the various CM assembly sites.

Turnkey

In the turnkey model, the CM negotiates with and buys directly from suppliers. Thus, the OEM can keep procurement overhead low while leveraging the CM's buying power and ability to break bulk, which can be a boon for small OEMs. Also the CM can pool the demand uncertainty of multiple OEMs to reduce the safety stocks. In principle, this efficiency should translate into low costs and high availability for the OEM.

The turnkey model carries many hazards, including forfeiture by the OEM of preferential treatment and loss of visibility into true procurement and material costs. For large OEMs and for noncommodity parts, the CM's procurement leverage will probably be weaker than the OEM's.

Turnkey with Audits

With this approach, the OEM retains the advantages of the turnkey model but adds auditing to detect errors and deter fraud, partially mitigating several hazards of pure turnkey. The OEM may perform the audits itself or rely on a specialist firm.

Through audits, OEMs can discover only a fraction of possible problems, may not gain full recovery of damages, and often lose the time value of money. They still forfeit preferential treatment and lose visibility into true procurement and material costs, while bearing the auditing expenses. When OEMs

believe they have greater procurement leverage than their CMs, they often choose from among the following procurement models.

Supplier Rebates

When OEMs believe they can negotiate superior prices and effectively monitor and collect private rebates from suppliers, they can obtain the same partial risk mitigation as they do with audits, because the information technology systems for tracking and collecting rebates essentially perform ongoing audits. In addition, suppliers can safely offer the OEM preferential pricing without revealing their prices to CMs and other OEMs. That is, this scheme achieves “price masking.”

The primary disadvantages of supplier rebates are the cost to the OEM for tracking and processing rebates and the costs to suppliers of negotiating prices separately with the CM and the OEM. Smaller OEMs and suppliers might find the administrative burden of the rebate scheme to be prohibitive. The CM is still ultimately the one paying the suppliers, and may use this role to enhance its own procurement leverage.

Buy–Sell

In the buy–sell model, the OEM buys directly from the supplier at a private price and immediately resells to the CM at a higher price. This achieves price masking and the benefits of maintaining direct OEM–supplier relationships. Once the buy–sell transaction is complete, the supplier delivers the materials directly to the CM.

The primary disadvantages for OEMs are the overhead required to manage procurement and any investment in systems and processes to enable buy–sell execution. In addition to maintaining supplier relationships, the OEMs must replicate the channel functions of a materials reseller.

Consignment

Consignment is an arrangement in which OEMs buy and own the inventory, which the CMs store. OEMs often use this model for parts that are unique, slow moving, proprietary, or scarce. OEMs can thus mask

prices and establish inventory buffers above those prescribed by the CMs’ standard policies. With consignment, OEMs are responsible for most of the procurement activities, reducing various risks but adding overhead costs.

An OEM need not limit itself to just one of these approaches, and many leading firms have developed the ability to execute many of them simultaneously. At the time of publication of Ref. 21, HP used buy–sell for strategic commodities (high value or coming from key suppliers), that is, the 20% of parts representing about half of its production spending. For the next 50% of parts, HP used audits (to verify pricing) and rebates (to mask pricing). HP allowed CMs to procure the remaining commodity parts in turnkey fashion.

OUTSOURCING OF LOGISTICS

Logistics, which many traditionalists view as the core activity of supply chain management, has a long history of outsourcing. A strong motive comes from the asset intensiveness of logistics (e.g., infrastructure for transportation, handling, storage, and increasingly, IT for real-time, global tracking at the individual package level of detail). At the same time, a strong enabler for the existence of logistics service providers is the fungibility of these assets across many customer and material categories. The value proposition of these service providers also includes an inventory dimension. Cycle stocks will decrease to the extent that clients feel relief from the need to completely fill containers or vehicles, greater delivery reliability reduces the need for safety stock, and pipeline inventories will be lower if the transit times are shorter. Service providers with an international footprint offer critical expertise in moving products through disparate physical, legal, and regulatory environments.

As with the broad supply chain functions discussed earlier, logistics can be divided into specialized elements, with labels such

as “freight forwarding,” “inbound logistics,” “warehousing,” “outbound logistics” (distribution), “service logistics” (for spare parts), and “reverse logistics.” All of these, as well as their smaller subtasks, are candidates for outsourcing. Some providers now offer nontraditional services such as light manufacturing, after-sale repair, packaging of products into store displays, and even financing of inventory.

Key terms for identifying the providers of logistics services are

3PL third-party logistics provider
 4PL fourth-party logistics provider
 LLP lead logistics provider

Lynch notes that “3PL” was first used in the early 1970s to identify intermodal marketing companies (IMCs) in transportation contracts [22]. Prior to that, transportation contracts involved only the shipper and the carrier. As intermediaries that accepted shipments from shippers and tendered them to rail carriers, IMCs became the third party to these contracts. Since then, the definition has broadened to refer to any company that offers a logistics service. “4PL” is generally attributed to Accenture, which registered it as a trademark in 1996 (while still known as Andersen Consulting). Accenture described the 4PL as an integrator, but today some consultants, software companies, and even 3PLs lay claim to being a 4PL. A 4PL can be thought to serve the function of general contractor. “LLP” is favored by some as a term with greater transparency than 4PL. Lynch [22] advocates using the following definitions.

3PL

According to the Council of Supply Chain Management Professionals, 3PL is a firm which provides multiple logistic services for use by customers. Preferably, these services are integrated, or “bundled” together by the provider. These firms facilitate the movement of parts and materials from suppliers to manufacturers, and finished products from manufacturers to distributors and retailers. Among the services which they provide are transportation, warehousing, cross-docking,

inventory management, packaging, and freight forwarding.

4PL

According to Accenture, 4PL is a supply chain integrator that assembles and manages the resources, capabilities, and technology of its own organization with those of complementary service providers to deliver a comprehensive supply chain solution.

LLP

Lynch defines LLP as a party that serves as the client’s primary supply chain management provider, defining processes, and managing the provision and integration of logistic services through its own organization and those of its subcontractors [22].

As with the other forms of supply chain outsourcing, a large body of practitioner literature provides advice on how to make the insource-versus-outsource decision for logistics and then how best to engage the service provider. In terms of the degree of difficulty of managing the outsourced relationship, logistics is comparable to design in being purely a service, but is comparable to manufacturing in the availability of relatively straightforward metrics such as delivery times and error rates.

THE OEM’S ROLE IN THE SUPPLY CHAIN OF THE FUTURE

In a world in which the ability to outsource nearly all supply chain functions have some joking that OEM must be an acronym for “Outsource Everything but Marketing,” one must wonder whether the OEM should still be considered the lead actor in the resulting ecosystem of codependent partners [23]. Some OEMs may evolve to a business model based on performing as supply chain “orchestrator” or “integrator,” such as the role played by the venerable Li & Fung or, increasingly in some of its electronics segments, Hewlett-Packard [24]. This resembles the function of the 4PL/LLP in logistics, but with a comprehensive scope.

Success in this role requires a core competence in managing complexity and designing mechanisms to contain transactions costs and moral hazards. As autocratic fiat does not exist in such extended enterprises, supply chain management takes on a political flavor in which negotiation and relationship-building prowess are the critical determinants of success [25]. How power, and hence profitability, will distribute across these supply chains will provide rich substrate for business research for years to come.

SUPPLY CHAIN RISK MANAGEMENT

MANMOHAN S. SODHI
Cass Business School,
City University
London, London, UK

CHRISTOPHER S. TANG
UCLA Anderson School,
Los Angeles, California

In addition, there are *strategic performance metrics* such as profits, market share, revenue growth, return on assets (ROA), and share price performance. Because disruptions to the supply chain can play havoc with these and other metrics, risk management for the supply chain has become an important emerging area for practitioners and researchers.

SUPPLY CHAIN RISK MANAGEMENT (SCRM)

SUPPLY CHAIN MANAGEMENT

A *supply chain* is a network of organizations possibly including suppliers, manufacturers, logistics providers, wholesalers/distributors, and retailers that aims to produce and deliver products or services for the end customer. *Supply chain management* is the management of material, information, and financial flows through the supply chain. It includes the coordination and collaboration of processes and activities across different functions such as marketing, sales, production, product design, procurement, logistics, finance, and information technology within the supply chain.

Supply chain management includes tracking and seeking to improve *operational performance metrics* including

- time-related measures such as product development cycle time, time to market, production lead time, replenishment/delivery lead time, cash-to-cash cycle;
- cost-related measures such as product development cost, material cost, production cost, labor cost, inventory cost, shipping and handling cost, sales and marketing cost, fixed and overhead cost; and
- customer satisfaction-related measures such as product availability, product and service quality, reliability, after sales support, and total cost of ownership.

During the 1990s and later, many firms implemented various supply chain initiatives to (i) increase revenue, for example, more product variety, more-frequent new product introductions, more sales channels/markets and new markets, (ii) reduce cost, for example, supply base reduction, on-line sourcing including e-markets and on-line auctions, offshore manufacturing, just-in-time inventory systems, and vendor managed inventory, and (iii) reduce assets, for example, outsourcing of manufacturing, information technology and logistics. Supply chains today are more “efficient” but also more complex than those in the past. As a consequence, they are also more vulnerable to disruptions and delays with large unanticipated consequences of seemingly contained events [1].

Such disruptions can have long-term stock price effects and equity risk effects. On the basis of an analysis of 827 disruption announcements made over a 10-year period, Hendricks and Singhal [2] found that companies suffering from the occurrence of uncertain events experienced 33–40% lower stock returns relative to their industry benchmarks over a three-year time period starting one year before and ending two years after the date announcing the event. The impact need not be financial alone: in 2007, over 100 brands of tainted pet food contaminated with the toxic chemical melamine killed thousands of dogs and cats in the United States. The impact of such incidents has led to a

growing interest in the area of “supply chain risk” and its management, as evidenced in the number of practitioner conferences and consultancy reports devoted to the topic [3].

Many executives and researchers started paying more attention to responding to severe disruptions after the attacks on September 11, 2001 [4,5]. However, it is important to manage risks in the larger context of coordinating supply and demand under various types of uncertainty.

While it is tempting to think of supply chain risk management (SCRM) as extending supply chain management to include risk, it is really a multidisciplinary area with research and practice that draws on *supply chain management*, *enterprise risk management*, and *crisis management*. These domains in turn draw on a broad swathe of the academic literature in areas such as organizational behavior, psychology, decision analysis, empirical analysis, stochastic modeling, and mathematical programming.

A consensus view from two supply chain conferences—Supply Chain Thought Leaders (SCTL) meeting in Madrid, 2008 and the International Supply Chain Risk Management (ISCRiM) workshop in Trondheim, 2008—is to consider SCRM as a subset of both supply chain management and of enterprise risk management. SCRM can also be viewed as a subset of crisis management and business continuity.

However, these parent areas each have a primary purpose different from that of SCRM. For instance, enterprise risk management tends to focus on risk disclosure in financial reporting of a company so as to comply with such regulations as the Sarbanes-Oxley Act in the United States or the KonTraG requirements in Germany. Likewise, supply chain management is primarily concerned with ways to improve the operational performance of a supply chain under “normal” circumstances. Crisis management focuses on the survival of the organization or even that of society and may seem distant from worries stemming from a delayed delivery of parts at a plant.

Still, we can draw on these domains, especially on enterprise risk management, to motivate viewing SCRM. Therefore, we

can view SCRM as comprising the four steps in enterprise risk management: (i) identifying risks, (ii) assessing these risks, (iii) mitigating these risks, and (iv) responding to incidents through communication and other means. The first three entail activities that take place *before* the occurrence of an incident that generates negative (and mostly) unanticipated consequences while the last one applies to actions taken *during* and *after* the occurrence of an incident—the focus here is on time, which is also called *time-based risk management* [6].

RISK IDENTIFICATION

Basic methods for identifying risks include identifying critical uncertainties in scenario planning [7], and charting different types of risk using taxonomy-based risk identification [8]. Scholars and practitioners have proposed different taxonomies. For instance, Juttner *et al.* [9] provide a classification of risks based on sources such as environmental risk sources, network risk sources, and organizational risk sources. Chopra and Sodhi [10] talk of delays and disruptions, while [11] discuss supply risk, process risks, and demand risks. In identifying risks, the terms *uncertainty* and *risk* have been used interchangeably in the supply chain literature although the economics literature has attempted to narrow risk to only those situations where the uncertain outcomes have a known probability distribution.

Broadly speaking, we can consider three types of risk motivated by supply chain management:

- *Supply Risks.* Supply risks relate to incidents that occur at different tiers of suppliers and threaten supplies to a company. These incidents include supplier defaults or other unexpected changes in supply cost, delivery, quality, or reliability. As many manufacturers reduced the number of direct suppliers so as to foster better supplier relationships, this form of supply risks is growing in importance [12]. Risks

related to outsourcing fall in this category.

- *Process Risks.* Despite significant efforts in implementing Total Quality Management (TQM), Lean Manufacturing, and Six Sigma, many companies are still facing risks from products produced as a result of faulty design or manufacturing. For example, because of unsafe toys with magnets designed internally by Mattel, Mattel recalled over 17 million toys in 2007. There are internal and external process risks in the manufacturing and service industries as well. For example, in 2004, IBM announced that yield problems at its plant in East Fishkill, New York contributed to the \$150 million first-quarter loss by its microelectronics division [13]. The lower-than-expected yields reduced the plant's effective capacity and limited IBM's ability to meet customer demand.
- *Demand Risks.* The uncertain nature of product demand is one of the supply chain risks that all companies need to face with uncertainty surrounding both volume and mix. For example, Hewlett-Packard (HP) developed multiple versions for each model of their DeskJet printers to serve different geographical regions, that is, Asia-Pacific, Europe, and the Americas. Owing to uncertain demand in each region, HP faced the problem of simultaneously overstocking some models of printers in one region while understocking the same in other regions.

There are also risks to the enterprise itself and hence to the entire supply chain. These include:

- *Intellectual property (IP) Risks.* While outsourcing or off-shoring can result in lower manufacturing costs, it makes it difficult to protect IP. For example, even though the reform of the IP protection law has made some good progress after China's WTO entry in 2001, some incidents can still occur there.

- *Behavioral Risks.* As the number of partners increases in a global supply chain, the level of visibility and control can be reduced significantly. The low visibility level and the low control level reduce the "confidence" of each supply chain partner regarding the following information: the replenishment lead time/order status quoted by upstream partners, and demand forecasts provided by downstream partners. Christopher and Lee [14] argue that a low confidence level can cause the entire supply chain to enter a "risk spiral" so that each supply chain partner either "inflates" their order or "disguises" their on-hand inventory because of the lack of confidence in the replenishment lead time and demand forecasts. The confidence level deteriorates further as every partner starts gaming the system, and hence, the "risk spiral" continues.
- *Political/Social Risks.* A global supply chain is subjected to social/political risks when multiple countries are involved. For example, Airbus, a four-nation consortium, incurred an opportunity loss of €4.8 billion due to a two-year delay in launching the Superjumbo A380. In addition to technical problems associated with the wiring system, political issues across the four countries with manufacturing plants to make these planes may be a reason. Airbus' parent, EADS has struggled to develop a restructuring plan to replace political bargaining with industrial logic [15].

RISK ASSESSMENT

For each identified risk, assessment involves estimating the likelihood of an incident occurring and estimating the consequences in case such an incident does occur. The consequences may include short-term and long-term financial losses, loss of human lives, and loss in brand equity. Zsidisin *et al.* [16] obtain common themes on supply risk assessment techniques and examine how different purchasing companies reduce

their supply risk. Where consequences are probability distributions, they may be “measured” as value-at-risk or VaR-based or related *risk metrics* [17].

A company may conduct *risk mapping* exercises to assess the likelihood of each risk that could occur and the associated consequences in case of an occurrence. Doing so helps focus on actions to reduce the overall impact that is possible from risks with low likelihood of an incident occurring but with potentially large consequences or from risks that have small impact per occurrence but can occur quite frequently.

The likelihood of a risk refers to the “occurrence frequency” of different uncertain events and based on this frequency—whether observed or subjective—the risk may be considered “normal” or “abnormal.” Frequent fluctuations of process yields, material costs, currency exchange rates, and product demands can be viewed as normal risks, while rare events such as natural/man-made disasters, contaminated products, and system failures are abnormal. Some researchers argue that managing normal risks is part of supply chain management while managing abnormal risks is the part of SCRM; however, the issue is really about who manages these risks in the organization rather than whether SCRM has normal risks in its scope or not.

We need to draw a distinction between the occurrence of uncertain events and the consequences: the uncertain event is the risk, while the eventual consequences (and to whom) depend on the actions taken by different parties after the event occurs. For example, from the viewpoint of many manufacturers, the terrorist attack on September 11, 2001 was an uncertain event, while the subsequent supply delays were a disruption directly caused by the suspension of air transportation.

Consequences may be local or global depending on whether the impact of the risk incident is limited to a particular location within the supply chain or whether the entire supply chain is affected. *Global consequences* impact the entire supply chain. For example, due to a recent surge in gasoline prices, Ford’s supply chain for SUV manufacturing

came to a halt in 2008 as consumers switched to compact cars; and Mattel suspended its production of toys after recalling over 20 million in 2007. *Local consequences* impact a particular market or a particular site. For example, Ford closed five plants in the United States for several days after all air traffic was suspended after September 11, 2001.

However, where an incident occurs may or may not be connected to where the consequences are felt. Thus, assessing supply chain risk entails understanding where a risk incident can occur (or is currently occurring) as distinct from where the consequences might be. We can categorize supply chain risks as being related to incidents that occur globally, spanning the entire supply chain, or those that occur locally at a particular supply chain entity only.

Global risks refer to uncertain events arising from the global environment within which the supply chain operates. These uncertain events include social or political instabilities, credit crunch crises, and commodity price increases.

Local risks refer to uncertain events that occur at one or more supply chain entities. Examples include natural disasters, labor union strikes, bankruptcies, contaminated production processes, or violation of IP rights at one or more supply chain entities. Local risks also include damaging behavior of certain supply chain partners.

We can thus assess supply chain risks by the “point of occurrence” and by consequence (Table 1) to set the stage for developing mitigation strategies. Identifying the point of occurrence of each type of risk and its consequences would create shared awareness of different types of risks and their potential impact on different supply chain parties. This process can enable supply chain partners to better define their roles and responsibilities and to generate support for collaborative efforts for mitigating risks for all parties. For example, after suffering from a “global” \$2 billion loss in sales that was caused by a “local” fire that disrupted the production of microchips at a supplier’s plant, Ericsson worked with its supply chain partners

Table 1. Supply Chain Risks and their Consequences

Supply chain risk (point of possible occurrence)	Consequences (Region of possible eventual impact)	
	<i>Local</i> (impact to a particular supply chain entity or market)	<i>Global</i> (impact to the entire supply chain or multiple markets)
<i>Local</i> (originating at a supply chain entity or in a particular market)	Local risks stemming from supply, demand, or failure match supply and demand	Risks originating in a plant or region whose consequences eventually impact the entire supply chain or markets
<i>Global</i> (originating supply chain-wide or globally)	Global risks that affect a particular supply chain entity	Global risks that can affect the entire supply chain as a whole

to develop proactive plans should an incident occur [18].

Clearly, the affected supply chain entity is responsible for reducing the local risk when the consequences are also local. Arguably, some of this is very much part of supply chain management, for example, maintaining inventory to reduce the impact of unexpected delays in supplies.

At the other extreme, for global risks that have global consequences, collaborative efforts from the entire supply chain would be needed at the corporate levels of companies. For example, to improve supply chain security, the Customs-Trade Partnership against Terrorism (C-TPAT) certification program was established in 2002 by the US Customs. This certification program requires all supply chain partners to comply with a standard operating procedure to ensure security. To entice companies to comply with the best security practices, C-TPAT certified companies are allowed to clear customs faster with less inspection [19].

To handle local risk with global consequences—some would argue this is really what SCRM should focus on—we need to understand both the role of the point of occurrence and the affected parties. For example, after recognizing the global consequence (Mattel's worldwide recall of lead-tainted toys) associated with a local risk (supplier was using lead-tainted paints to produce toys), Mattel announced a safety check system to prevent the manufacture of toys with noncompliant levels of lead in paint [20].

Finally, situations entailing global risk with local consequences are usually the result of corporate policy applied inappropriately or incorrectly to a local situation. For instance, there may be local negative consequences of a corporate procurement policy. This can be mitigated only by communication between the local facilities with the corporate entity.

RISK MITIGATION

Once a particular supply chain risk is identified, assessed, and selected for mitigation, it can be mitigated by decreasing its likelihood, reducing its potential consequences or both. Paulsson and Nilsson [21] present 23 methods for mitigating risks; however, there are three basic approaches: *accept*, *avoid*, and *reduce*. *Accepting* the risk does not require doing anything other than the company bearing the entire consequence in case there is a risk incident or transferring part of the consequences to its insurance company or to its supply chain partner. Transferring risk through insurance or through financial instruments like swaps does not actually reduce the likelihood of the risk. Even if it reduces the impact of the risk to a certain extent, it may result in moral hazard whereby the company can become more risk-prone knowing that it can transfer some or all of the financial consequences. Likewise, liability insurance may offer financial compensations to customers who suffer from using unsafe products, but it does not reduce the damage to the reputation of the company

nor the suffering of the people who used these products.

Avoiding risks entails efforts to reduce the likelihood of the occurrence of certain undesirable incidents. Such efforts include the development of fail-safe systems, that is, systems that cannot fail or that can trigger corrective actions to prevent failures, and the application of quality-based principles to ensure there is no failure in the detection of a risk incident with highly negative consequences. Such approaches can be quite useful in security-related risks where preventing an incident from ever happening is the best approach. Lee and Wolfe [22] illustrate how certain technologies, say, biometric systems for positive identification of personnel and smart container systems for monitoring the internal temperature and pressure of each container, can be used to prevent containers being tampered with throughout the shipping process. The US Homeland Security has developed the Container Security Initiative (CSI) that requires all containers to be pre-screened at the port of departure before they arrive at US ports to reduce the likelihood of seaport terrorist attacks in the United States.

Reducing risk impact entails efforts to reduce the impact of risk incidents in case such incidents do occur. Broad approaches in this category are (i) alignment of supply chain partners' incentives, (ii) the use of "buffers" or redundancies, and (iii) flexibility.

1. *Alignment.* Besides long-term partnerships, there are other mechanisms to coordinate the interests of the different supply chain partners. Tang [23] reviewed different types of supply contracts to coordinate a supply chain so that all parties will act in the interest of the entire supply chain when dealing with demand risks including *wholesale price contracts*, *buyback contracts*, and *revenue sharing contracts*. A two-part tariff, that is, a fixed cost and a per unit wholesale price, can be used to entice the downstream partner to order according to the optimal order quantity (as per the newsvendor solution) for the entire supply chain. A buy-back contract is a returns policy under

which the manufacturer is required to buy back the retailer's excess inventory at a reduced price. Under certain conditions, doing so can achieve supply chain coordination. Under a revenue sharing contract, the retailer shares the revenue with the manufacturer and obtains a reduction in the wholesale price in return, achieving supply chain coordination. Narayanan and Raman [24] have studied *risk sharing* and revenue sharing to align incentives across supply chain partners.

2. *Buffers for Redundancy.* Firms can always build in some redundancies throughout the supply chain so as to reduce the cost implications of certain undesirable events associated with supply, process, and demand risks; Chopra and Sodhi [10] refer to these as *buffers* against supply chain risk. For example, extra inventory, extra back-up production capacity, and extra back-up suppliers are buffers against delays and disruption in the supply chain. However, Sheffi [4] argues that redundancies can be expensive when used against (rare) unanticipated events. Also, redundancies disguise inefficiencies in the supply chain, inhibiting the achievement of a lean supply chain. Flexibility overcomes these disadvantages: it can reduce the impact of the occurrence of certain unanticipated events and it can also be put to use with planned changes, for instance, to produce a greater variety of products.
3. *Flexibility.* Tang and Tomlin [11] analyze five different types of flexibility strategies corresponding to *multiple suppliers*, *flexible supply contracts*, *flexible manufacturing process*, *postponement*, and *responsive pricing*. The ability to shift order quantities across suppliers can be a powerful mechanism for the manufacturer to hedge against supply risks. Under flexible supply contracts, the manufacturer is allowed to adjust the order quantity within a prespecified range, say, a few percent of the order quantity. This helps to

mitigate the impact associated with demand risks [25]. The manufacturing process is flexible if different types of products can be manufactured in the same plant, enabling the manufacturer to reduce supply, process, or demand risks [26]. Postponement calls for delayed product differentiation by producing a generic product initially and then customizing it for different markets and customers later, thus allowing a company to respond to demand changes across multiple markets quickly [27]. Responsive pricing is an effective tool to mitigate supply or demand risks by manipulating demand when the supply is inflexible. For example, as the supply of certain components from Taiwan was affected by an earthquake, Dell's response was to lower the price of certain products so as to entice their on-line customers to "shift" their demands to other Dell computers that utilized components from other countries.

Similar to the above, Lee [28] recommends the principles of alignment, agility, and adaptability and provides industry examples for reducing the impact associated with different types of supply chain risks. Alignment calls for aligned interests among supply chain partners so as to facilitate close communication, cooperation, and collaboration; agility entails flexibility and responsiveness; and adaptability requires close monitoring of the environment so that one can deploy a recovery plan in a timely manner.

RISK RESPONSE AND COMMUNICATION

When a company cannot prevent a risk incident from occurring or mitigate it as described in the previous section, it has to figure out ways to respond quickly so as to contain the damage. The focus is really on time and therefore Sodhi and Tang [6] called it *time-based risk management*. Communication is a part of *crisis management* that is also needed as a response to untoward incidents.

Once the supply chain partners have identified and assessed certain types of supply chain risks and developed certain risk mitigation plans based on either the alignment or the agility strategies, it remains to develop adaptive capabilities for quick response to risk incidents, that is, reduce response lead time comprising of (i) the time to *detect* a risk incident, (ii) the time to *design* one or more solutions as well as *selecting* one solution in response to the incident, and (iii) the time to *deploy* the solution. Companies can reduce the impact of supply chain risk incidents by shortening these three elements of time and hence the response time. After deployment, the time it takes to restore the supply chain operations is the recovery time.

If the response lead time is short, the eventual impact will be lower as well—if not, the company is better off pursuing risk avoidance as discussed earlier. To understand the impact of response lead time on total impact of a risk incident, consider the case of Med fly (Mediterranean fruit fly) eradication in California in 1980. Instead of calling for an effective but costly aerial spray of Malathion in a small area of 30 square miles, Governor Brown chose to go with releasing sterile male flies and traps and within 12 months, the area of infestation expanded more than 20-fold. Local consequences became global over this time and Japan and other countries imposed import restrictions. Eventually, aerial spray had to be done over an area of 1500 square miles starting on July 14, 1981. This delayed action came at a significant cost: an expenditure of over \$100 million and Governor Brown's political career [29].

Detection time can be reduced by developing mechanisms to discover a risk incident quickly when it occurs or even to predict it before it occurs. Companies must also identify ways to share the information with their supply chain partners. Monitoring and advance warning systems can enable firms to reduce the detection lead time. For instance, many firms have various IT systems for monitoring the material flows (delivery and sales) and information flows (demand forecasts, production schedule, inventory level, quality) along the supply chain on a regular basis. For example, Nike has a "virtual

radar screen” for monitoring its supply chain operations [30]; Nokia monitors the delivery schedule of suppliers; and Seven-Eleven Japan monitors the production/delivery schedule from their vendors (suppliers) as well as the point of sales data from different stores throughout the day [31]. Such monitoring systems typically use various types of control charts (see **Supply Chain Coordination**) to monitor the operations and to issue an alert should any anomaly occur. Advance warning systems, by contrast, are intended to detect an undesirable event before it actually occurs, thus reducing detection time to a minimum. For example, smart alert systems enable GE to conduct remote-sensing and diagnostics, so that it can deploy engineers to service turbines before catastrophic failures occur. *Design time* would be reduced if the company and its partners can develop contingent recovery plans for different types of disruptions *in advance*. Many organizations seek to do so through *business continuity* efforts. For example, Li and Fung has a variety of different contingent supply plans to enable them to switch from one supplier in one country to another supplier in a different country [32]. Seven-Eleven Japan has developed contingency delivery plans to enable them to switch from one transportation mode (trucks) to another (motorcycles), depending on traffic conditions [31]. A company may find it useful to use decision analysis tools such as decision-tree analysis (see **Describing Decision Problems by Decision Trees**) to refine and select a recovery plan. Sarin [33] presents a decision-analysis framework for evaluating different earthquake-safety plans.

Deployment lead time can be shortened by improving communication and coordination among supply chain entities within the company or within supply chain partner firms, once a recovery plan has been selected. Van Wassenhove [34] suggested three forms of coordination: (i) by command (central coordination), (ii) by consensus (information sharing), and (iii) by default (routine communication). In the event of a major disruption, coordination by command seems to be more appropriate during the design phase of a

recovery plan and its deployment. Once the recovery plan is deployed, coordination by consensus would seem appropriate especially when each party has a clear role and responsibility established in advance.

Communication, an important aspect of *crisis management*, is also a time-based response approach motivated by public perception. Companies need to develop crisis management plans to manage the public perception so as to reduce the long-term impact on the company’s reputation. Immediately after a risk incident, the involved supply chain parties need to develop plans to restore customer relationship and communicate their approach for rebuilding public confidence. For example, immediately after Mattel issued multiple recalls in 2007, it created simple ways for consumers to return the recalled products using downloadable forms, and free shipping mailers. To restore trust, the company acknowledged problems to stakeholders and apologized to customers publicly in the press. In exchange for returned toys, it offered coupons for customers to buy other Mattel products of the same value. It also announced the three-stage safety check system in September 2007: test every batch of inputs (paint); test every batch of production; and test samples of finished goods from each production run. In addition to external communication, internal communication is important to facilitate organizational learning to improve better manage supply chain risk in the future [35]. At Mattel, a new position was created reporting directly to the Mattel’s CEO to ensure that potential recall risks were quickly addressed, and, if necessary, elevated within the company for improved internal communication [36].

CONCLUSION

We have described SCRM referring to its roots in the disciplines of supply chain management, enterprise risk management, and crisis management. We chose the enterprise risk management approach of viewing risk management in terms of (i) risk identification, (ii) risk assessment, (iii) risk mitigation, and (iv) risk response and communication.

While rooted in these disciplines, SCRM is not fully a part of any of these. SCRM is not a part of supply chain management although good supply chain management needs to include principles of SCRM. Likewise, SCRM is not a part of enterprise risk management, although to do effective enterprise risk management, a company needs to excel in SCRM. Finally, SCRM is not part of crisis management and business continuity, although if the supply chain experiences a crisis, then any solution to crisis management has to incorporate SCRM as we saw from Mattel's example. Thus, SCRM is important not just to supply chain professionals but to others as well. Given its growing importance to companies, it is likely it will be viewed as a discipline in its own right.

SUPPLY CHAIN SCHEDULING: ORIGINS AND APPLICATION TO SEQUENCING, BATCHING AND LOT SIZING

NICHOLAS G. HALL

Department of Management Sciences,
Fisher College of Business, The Ohio
State University, Columbus, Ohio

This article discusses supply chain coordination at the detailed, operational level. Work in this area is motivated both by the practical importance of the problems studied and the wide variety of interesting research questions. Thomas and Griffin [1] provide a detailed review of the literature of supply chain management. They indicate that over 11% of the US Gross National Product comes from nonmilitary logistics expenditures. In fact, for many products, logistics expenditures account for more than 30% of the cost of goods sold. The authors identify a need for research that addresses supply chain issues at an operational rather than a strategic level, and that uses deterministic rather than stochastic methodology to analyze them. The recent development of the supply chain scheduling research area, which is the subject of this article, addresses both these requirements.

Further motivation for this article is provided by a survey of integrated production and distribution models by Sarmiento and Nagi [2]. As they point out, the recent trend toward lean manufacturing and reduced inventory levels [3,4] has created a closer interaction between the adjacent stages of a supply chain. This is because inventory can no longer be used as a buffer between poorly coordinated schedules. This, in turn, increases the need for coordination in scheduling and other related decisions between various decision makers with different costs, constraints, and objectives.

The need for coordinated operational decision making of the type discussed here arises in applications with short time

horizons, which reduces the usefulness of models for strategic decision making. Related applications include customized and assemble-to-order products, fashion items, and seasonal products. Relevant examples of manufactured goods include electronics products, apparel, toys, and perishable food products. Among the typical characteristics of these goods are that the products are time sensitive and the orders are distinct. For a more detailed discussion of these applications, see *Coordination of Production and Delivery in Supply Chain Scheduling* in this encyclopedia.

When a set of jobs needs to be manufactured, the cost and feasibility of scheduling them often depend on the *sequence* in which they are processed. Pinedo [5] provides many examples. In some manufacturing environments, a sequence of the jobs that is both feasible and cost minimizing can be found by an indexing rule based on their characteristics. In other environments, a more complex algorithm is required, but a cost-minimizing sequence can still be computed in a reasonable amount of time. However, in a third group of environments, the sequencing problem is formally intractable [6], and hence finding a cost-minimizing sequence is likely to be computationally possible only if the number of jobs is small. In this last case, scheduling decisions for practical size problems are often made heuristically, which usually results in solutions that do not minimize cost.

An example of mutually incompatible decision making between a supplier and a manufacturer occurs in sequencing the production of jobs. Suppose that a supplier uses a particular preferred sequence of jobs that reduces its sequence-dependent setup costs. Further, suppose that, in order to reduce the supplier's inventory holding cost, these jobs are delivered individually to a manufacturer in the production sequence preferred by the supplier. Problematically, the manufacturer may have completely different sequence-dependent setup costs

that suggest a very dissimilar processing sequence. The manufacturer then has various options, none of which is necessarily favorable. First, it can follow the sequence used by the supplier, which controls holding costs but incurs high setup costs. Second, it can store the jobs as needed until enough of them have arrived that it can use its preferred sequence, which controls setup costs but incurs high holding costs. Solutions that interpolate between these two possibilities in various ways are also available. The decisions of the supplier affect the costs of the manufacturer, but the converse is not true. Therefore, the manufacturer can provide incentives to the supplier to change its job delivery sequence to be more compatible with the preferred processing sequence of the manufacturer.

Several modern extensions of classical scheduling theory address issues of conflicting objectives or competing agents. First, multicriteria scheduling [7,8] discusses problems faced by a single decision maker who measures cost in multiple ways. Although this research does not model supply chains, the use of Pareto optimality suggests some approaches that can be useful in that context. Second, integrated scheduling [9,10] considers operational issues across multiple stages of the supply chain within a single organization. Although there are no competing agents, conflicts naturally arise between decisions at different stages. For

example, the optimal production sequence may need to be modified in order to control transportation costs. Third, sequencing games [11–13] consider multiple agents within the same stage of production. If the agents can cooperate, the overall cost of the system is reduced. The focus of this research is on the existence of core solutions and related concepts within cooperative and bargaining games [14], rather than optimization of the overall system cost. Finally, supply chain scheduling [15,16] considers problems with multiple agents across multiple supply chain stages. The supply chain scheduling literature evaluates the benefit of coordination for the overall supply chain, and makes prescriptive statements about how to achieve coordination. Table 1 describes the main features of these four extensions, thereby illustrating the origins of supply chain scheduling and its relationship with other modern extensions of classical scheduling theory.

In multistage supply chains, *batching* involves processing and/or transporting several jobs contiguously. One motivation for batching is to reduce setup times or costs that occur when different types of items are produced consecutively. Examples arise in the chemical, food processing, and fertilizer industries. A second example arises in the manufacturing of engineering components, where the principles of group technology [17] can be used to organize the components into

Table 1. Modern Extensions of Classical Scheduling Theory

Topic	Multicriteria Scheduling	Integrated Scheduling	Sequencing Games	Supply Chain Scheduling
Number of agents	One	One	Many	Many
Number of stages	One or two	Two	One	Two or more
Optimization of system cost	Yes	Yes	No	Yes
Evaluation of benefit of coordination	No	Yes	Yes	Yes
Agents have distinct jobs	No	No	Yes	Yes
Prescriptive mechanisms	Pareto, optimization	Optimization, heuristics	Game theory, allocations	Incentives, game theory
Early reference	Nelson <i>et al.</i> [7]	Maggu <i>et al.</i> [9]	Curiel <i>et al.</i> [11]	Hall and Potts [14]
Recent reference	Hoogeveen [8]	Lee and Chen [10]	Agnetis <i>et al.</i> [12]	Hall and Liu [15]

families with enough similarity that setups are not needed between the processing of their components. A second motivation for batching arises from transportation cost savings. When a supplier ships to a manufacturer, a transportation cost is incurred. Batching of more jobs reduces the number of shipments and thus the total fixed cost of transportation. A third motivation occurs where several jobs are naturally processed in a batch, for example as with burn-in operations in semiconductor manufacturing [18].

Chen [19] provides a comprehensive review of batching within the integrated scheduling literature. Lee and Chen [10] study the integration of batching issues in transportation, including those related to time and capacity, with scheduling decisions. Two types of transportation are considered: the transfer of semifinished jobs in batches from one processing facility to another using automated transporters, and the delivery of finished goods in batches to warehouses or customers using trucks. Both transportation capacity and transportation times are considered. The focus of the work is on the solvability of a variety of integrated scheduling problems, including the design of efficient algorithms and proofs of intractability. In addition, the work describes a heuristic for one of the intractable problems studied, and analyzes its worst case performance. This work is motivational for the topic of supply chain scheduling, but considers neither multiple decision makers with conflicting objectives and distinct job sets nor the design of incentives that result in effective coordination of scheduling and other related decisions.

An issue that is closely related to batching is *lot sizing*, which is the decision on how and when to split a production lot of identical items into sublots. In a multistage supply chain, the use of sublots permits the overlapping of different operations on the same production lot, in order to reduce throughput time. Thus, the use of sublots by a supplier effectively reduces the arrival times of jobs at the manufacturer, which makes the scheduling problem of the manufacturer less constrained. However,

except under vendor-managed inventory [20] (see *Vendor-Managed Inventory*), this also means that the manufacturer is responsible for the inventory holding cost of the subplot at an earlier time. The resulting trade-offs depend on the relative costs of production setups, holding inventory and delivery. Depending on these trade-offs, the manufacturer may wish to provide incentives to the supplier to change its lot-sizing policy.

We discuss some examples of lot-sizing models in multistage supply chains, with the objective of minimizing the total of ordering and holding costs. Monahan [21] shows how a supplier can use a price discount to encourage a manufacturer to order in larger lot sizes, which benefits the supplier. This model is generalized by Lee and Rosenblatt [22], who introduce the practical realities of a limit on the discount that can be offered and different lot sizes for the supplier and the manufacturer. They describe an algorithm for the supplier's joint price discount and ordering problem. Sensitivity analysis results show that the amount of price discount which the supplier should offer depends on the costs of both parties. These works are motivational for coordination issues that arise in supply chain scheduling, but fail to consider timing issues and costs at the individual job level.

As with sequencing decisions, batching and lot-sizing decisions are difficult to make in some planning environments. An additional complication is that effective decision making often requires that sequencing, batching, and lot-sizing decisions be made jointly rather than separately. Within supply chains, still another complication is that the self interested sequencing, batching and lot-sizing decisions of a supplier and a manufacturer may not be mutually compatible. In such cases, the overall performance of the supply chain is adversely affected, sometimes severely, by poorly coordinated decision making.

Potts and Van Wassenhove [23] and Potts and Kovalyov [24] provide detailed reviews of the literature of scheduling in combination with batching and lot sizing. We discuss some

early work on coordination issues in production and distribution systems with multiple stages. Ow *et al.* [25] describe a multiagent scheduling system. Lee *et al.* [26] consider a scheduling problem that arises in a two-stage assembly system consisting of two suppliers and one manufacturer. They discuss the solvability of this problem, and describe both exact and approximate solution procedures. Potts *et al.* [27] consider a more general problem with several suppliers and one manufacturer. They describe approximate solution methods, and study their worst case performance. The focus of all these papers is on optimization and approximation results. Indeed, none of these papers provides a detailed analysis of cooperation between decision makers with different and possibly conflicting objectives. The supply chain scheduling papers, discussed in the next section, do achieve this.

SUPPLY CHAIN SCHEDULING LITERATURE

We first introduce a prototypical real-world supply chain scheduling problem. Boros *et al.* [28] consider a supply chain consisting of a foreign shipping company and a domestic port. The main decision to be made is the lot size with which the shipping company removes the empty containers from the domestic port, so that the joint profit of the two agents is maximized. The two agents have conflicting interests regarding this lot size. The shipping company prefers larger lot sizes and longer cycle times, which require fewer trips by its shipping vessels. However, the port prefers smaller lot sizes and shorter cycle times, which reduce the accumulation of the empty containers and their storage cost. The paper proposes an iterative heuristic to search for the lot size that maximizes the overall system profit. At each iteration, a candidate lot size is evaluated using a deterministic vehicle scheduling problem and a stochastic container storage capacity optimization problem. On the basis of the results of a computational study that includes 300 randomly generated problem instances, the heuristic delivers solutions that are usually within 1% of the optimal profit across

a wide range of parameter settings. However, the optimal lot size for the system is, in general, not optimal for either the shipping company or the port. As a result, each party requires an incentive to adopt a lot size that is different from its optimal choice. More generally, this outcome is common in supply chain scheduling problems. In most situations, cooperation by the parties generates substantial savings for the overall system. In many cases, it is possible for them to agree a distribution of these savings that ensures cooperation.

The earliest supply chain scheduling paper, by Hall and Potts [15], considers scheduling and batching problems with three different objectives in a supply chain where a supplier delivers to several manufacturers, who in turn deliver to customers. The supplier acts to minimize the total of its sequencing and batching cost. The supplier's sequencing and batching decisions define the arrival times of the jobs at the manufacturer. Then the manufacturer, given these arrival times, acts to minimize the total of its sequencing and batching cost. The decisions of both players are made using optimal dynamic programming algorithms. The optimal joint sequencing and batching decisions of the supplier and manufacturer, acting together to minimize the total supply chain cost, are also found similarly. Example instances show that the solution which results from the supplier and manufacturer acting independently can be considerably more costly than the solution of the combined problem. Further instances show that an optimal combined solution may not be a Nash equilibrium. This is because the supplier benefits from unilaterally changing its solution, even though the supply chain as a whole incurs larger cost. However, some simple mechanisms exist that can be used to obtain the supplier's cooperation in choosing the overall optimal solution. These mechanisms include the manufacturer offering an incentive for the supplier to deliver all the jobs together, and offering to share holding costs for completed jobs at the supplier.

Dawande *et al.* [29] study a real-world supply chain where a manufacturer makes

products that are shipped to customers by a distributor. The manufacturer chooses a schedule that minimizes unproductive time. This schedule uses long production runs in order to reduce the number of production setups. However, the distributor optimizes either customer service relative to due dates or inventory holding cost, and consequently prefers a different schedule to the manufacturer. If each party follows its own preferred schedule, then the overall supply chain is not well coordinated and its performance, as measured by total system cost, is typically poor. The results in the paper include measurement of each player's conflict, which is the relative increase in cost that results from using the other player's optimal schedule, relative to its own optimal schedule. This conflict is often significant, which motivates the study of coordination. How this conflict is resolved depends on the balance of power within the supply chain. Models are analyzed for situations where the manufacturer has dominant power, and for other situations where the distributor has dominant power. Finally, by solving the problem where both players cooperate fully, it is possible to evaluate the benefit of cooperation. Since achieving full cooperation typically requires the dominant player not to implement its optimal schedule, incentive mechanisms are developed to ensure its cooperation. Examples of such mechanisms include lump sum side payments, and contributions by the distributor toward the cost of additional production setups by the manufacturer.

Agnetis *et al.* [30] consider a two-stage supply chain consisting of a supplier and several manufacturers. A schedule is fully determined by a sequence. The supplier and each manufacturer have a different ideal sequence for processing the jobs, which is determined by its production changeover costs. An intermediate storage buffer of limited capacity is available to resequence the jobs after the supplier processes them, but before they reach the manufacturers. The paper considers the minimization of total changeover plus buffer storage cost. Efficient algorithms are described for the problems faced by the supplier and by each manufacturer individually. It is shown that

cooperation between the supplier and the manufacturers in sharing buffer cost can reduce the overall supply chain cost.

Chen and Hall [31] consider a two-stage assembly system where several suppliers provide parts to a manufacturer. A product cannot start processing at the manufacturer until all its parts have been supplied. The manufacturer performs nonbottleneck operations, for example, through outsourcing. The objectives considered are the minimization of the total completion time, and the optimization of a customer service measure which is either the total completion time or the maximum lateness of the latest job. The results begin with an analysis of conflict, that is, how far from optimal the best suppliers' schedule is when applied to the manufacturer's problem, and vice versa. For the total completion time problem, a lower bound on the manufacturer's conflict when using the suppliers' schedule is derived analytically and evaluated computationally at between 19% and 83%, depending on the data. Conversely, following the manufacturer's optimal schedule gives a conflict of between 3% and 37%, when used for the suppliers' problem. If the manufacturer uses maximum lateness as an objective, then following the suppliers' schedule results in very large conflict that increases with the number of suppliers. Conversely, using the manufacturer's optimal schedule results in a conflict that is between 1% and 49% in the suppliers' problem.

Motivated by these substantial levels of conflict, Chen and Hall [31] study four scenarios for bargaining power in the supply chain. First, if the suppliers dominate and the manufacturer negotiates with them by compensating the suppliers for using a different schedule, sufficient compensation can always be made to ensure that an optimal supply chain schedule is achieved. Second, if the manufacturer dominates and the suppliers negotiate, a similar result is achieved. Third, if the manufacturer dominates and does not accept negotiation from the suppliers, the manufacturer's solutions can be modeled as constraints within the suppliers' problem. Fourth, if the parties cooperate, sufficient conditions are described for compensating the

players to follow the system optimal schedule; whether those conditions are met depends on the problem data. Finally, the relative cost saving from cooperation between the suppliers and the manufacturer is evaluated. When all players use completion time as an objective, this ranges between 0% and 27%. When the manufacturer uses maximum lateness as an objective, the relative cost saving ranges between 1% and 83%. The possibility of sharing these substantial cost savings provides a strong incentive for the players to cooperate.

Manoj *et al.* [32] consider the benefit of coordinated decision making in a supply chain consisting of a manufacturer, a distributor, and several retailers. The distributor batches finished goods produced by the manufacturer, manages their inventory, and delivers them to the retailers. The costs of conflict are substantial. If a dominant manufacturer imposes its optimal schedule on the distributor, the result is typically an increase in the distributor's holding cost of between 52% and 75%. Consequently, the distributor may provide an incentive for the manufacturer to change its schedule. Conversely, if a dominant distributor imposes its optimal schedule on the manufacturer, the result is typically a several hundred percent increase in the manufacturer's production costs from changing production rates. In this case, the manufacturer may provide an incentive for the distributor to change its batching and delivery schedule. The benefit of cooperation from coordinated decision making by the manufacturer and distributor is also discussed. Where the manufacturer has dominant market power, cooperation results in a cost reduction for the distributor of between 28% and 37%. Where the distributor has dominant market power, the manufacturer's cost reduction is between 45% and 57%. These savings are typically sufficient to ensure the cooperation of both parties when incorporated in simple incentive mechanisms.

The following insights appear consistently within the supply chain scheduling literature.

1. There exist several reasons why different parties within a supply chain naturally make scheduling, lot sizing, and batching decisions that are mutually incompatible.
2. The cost of conflict imposed by a party with dominant power on other parties is usually considerable, and, in practice, quite likely to lead to the breakdown of the supply chain partnership if implemented.
3. The willingness of parties to cooperate with others depends not only on their relative market power but also on their relative positions upstream or downstream within the supply chain.
4. When the parties have approximately equal power in the supply chain, it is sometimes but not always the case that they can achieve and maintain coordination. Even for the same problem environment, whether this is possible may depend on problem data.
5. The saving in total supply chain cost that results from the coordination of sequencing, batching, and lot-sizing decisions is usually considerable.
6. The more costs are considered, the greater is the possibility for cooperation between the parties to reduce the total system cost.
7. Incentive mechanisms need not be complicated in order to ensure coordinated decision making; indeed, simple side payments are one of the most effective incentives in many supply chain scheduling problems.
8. An optimal cooperative solution is not always a Nash equilibrium, therefore verifiability may be needed to ensure stable decision making.
9. The greater the savings from cooperation between the parties, the easier it is to design incentives that will lead to a supply chain optimal solution.

SUMMARY

Research in supply chain scheduling analyzes the coordination of operational

decisions in supply chains. Conflicts over operational decisions such as sequencing, batching, and lot sizing arise naturally in many real-world supply chains, for example because of differences in relative costs between different supply chain members. Since the decisions being made are operational ones with short time horizons, more reliable data is available than in other supply chain planning environments. This permits more accurate estimation of the benefits of supply chain coordination, for example through optimization models, and therefore better decision making about when such coordination is worthwhile. Because the study of supply chain scheduling is relatively new, there are many opportunities for designing incentive schemes that encourage supply chain coordination in operational decision making. Because different decisions and costs are considered, successful incentive schemes may be different from those in traditional supply chain management. As discussed in *Capacity Allocation in Supply Chain Scheduling*, cooperative game theory models should yield valuable insights about the stability of cooperation between decision makers in various applications. The rapidly evolving literature of supply chain scheduling already includes a journal special issue devoted to this topic [33].

INTRODUCTION

The ability of intelligent learning to apply what we have learned to new situations is called *generalization* [1–9]. Support vector machines (SVMs) are a family of learning algorithms first introduced by Vapnik [7], which are developed on this generalization concept. The SVM learning problem can be cast as a quadratic programming problem and other formulations result into a linear programming problem. In contrast to other learning networks, the resulting SVM optimization problem is convex with a global optimal solution. SVMs can discriminate between classes that are linearly *separable*, linearly inseparable, and nonlinearly separable. They work by maximizing the *margin* between two classes of training data that is, maximizing the distance between an affine hyperplane separating the two classes of data while avoiding overfitting the result by using a regularization process.

SVMs integrate the classification pattern learned from many training examples and determine a rule that maps inputs to their most probable classes. The learned rule has a good generalization behavior if it does as well as on new inputs as on the old ones. A classical result in learning theory shows that the function learned through the empirical risk minimization principle generalizes well if the *hypothesis* space from which they are chosen is *simple* [9]. The classical definition of a simple hypothesis space (a space with

low complexity) is technically involved. An example of a simple hypothesis space is the set of linear functions defined on the plane: the complexity of this set of functions or *VC dimension* is three since this is the greatest number of points in the plane belonging to two distinct classes that can be arranged so that suitable linear functions can separate them.

More recent work [10] shifts attention from the hypothesis space and concentrates on the concept of stability of learning algorithms. In simple words, a learning algorithm is stable if the removal of a training sample from a large set of samples results in a small change in the learned function. SVMs enjoy this stability property. Moreover, they are stable with respect to data perturbations. An advantage of SVM is the natural use of *kernel methods* that provide the ability to perform a mapping of the observed data into a high-dimensional (possibly infinite-dimensional) Hilbert space, thus, providing an avenue for exploring nonlinear binary classifiers [2,11].

SVMs have been applied to a wide range of problems such as computational biology [12–14], fluid mechanics [15–17], manufacturing engineering [18], meteorology [19–21], and even political science [22]. Recently, SVMs have been applied to short-term portfolio management [23], exchange rate prediction [24], and stock price prediction [25,26]. Other interesting applications are in the area of production [27], inventory transactions [28], bioinformatics and gene analysis [14,29], and web mining [30]. SVMs also have applications in manufacturing [31,32] and other domains, which are described in the special issue on Support Vector Machines and Applications of *Computational Management Science* [33].

The article is organized as follows. In the section titled “Binary Classification with Support Vector Machines,” the binary classification with SVMs is discussed. Multiclass classifications schemes are discussed in the section titled “Multiclass Classification Schemes.” The section titled “Machines

Based on Central Representations of the Version Space” provides improvements of SVMs and discusses computational issues, followed by the conclusion section.

BINARY CLASSIFICATION WITH SUPPORT VECTOR MACHINES

Consider a classification problem for which one has to find a *decision rule* that will evaluate if an *observation* represented by a vector $\mathbf{x} \in \mathbb{R}^n$ belongs to either one of two distinct *classes* arbitrarily labeled “A” and “B.” To do so, a *training set* $S = \{(\mathbf{x}_i, y_i) \in \mathbb{R}^n \times \{-1, 1\} : i \in [1, m]\}$ of m pairs of n -vectors and their *label values* is initially given with the *convention* that the label value is -1 if the corresponding vector belongs to class A and 1 otherwise. The decision rule to be built from S is, therefore, a function $f : \mathbb{R}^n \rightarrow \{-1, 1\}$ that conventionally depends on some other real-valued function g over $\mathbb{R}^n$ such that

$$\begin{cases} f(\mathbf{x}) = -1 & \text{if } g(\mathbf{x}) < 0, \\ f(\mathbf{x}) = 1 & \text{otherwise.} \end{cases}$$

In SVM theory, one attempts to *map* observations into some *Hilbert space* $\mathcal{H}$, also called *feature space*, using the set S and the function g as an algebraic measure of distance from an *affine hyperplane* dividing $\mathcal{H}$ into two *half-spaces*, one half-space for mapped points belonging to class A and one half-space for mapped points belonging to class B. The mapping itself is realized with the help of the *kernel trick* for which a continuous, symmetric, and positive semidefinite function $k : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$, also called *kernel function* or *kernel*, can be expressed as a dot product in a Hilbert space. Since an affine hyperplane in $\mathcal{H}$ that has a normal vector $w \neq 0$ and a bias $b \in \mathbb{R}$ is the set $\{x \in \mathcal{H} : \langle w, x \rangle_{\mathcal{H}} + b = 0\}$ where $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ is the dot product in $\mathcal{H}$, one may define $\mathcal{H}$ as the space which dot product is *implied* by a given kernel k . If a kernel k is defined, then, by Mercer’s theorem, there exists a map $\phi : \mathbb{R}^n \rightarrow \mathcal{H}$ such that $k(\mathbf{w}, \mathbf{x}) = \langle \phi(\mathbf{w}), \phi(\mathbf{x}) \rangle_{\mathcal{H}}$ for all $(\mathbf{w}, \mathbf{x}) \in \mathbb{R}^{2n}$. Combining the kernel trick with the notion of algebraic distance from an affine hyperplane in $\mathcal{H}$, the function g then takes the form $g : \mathbf{x} \mapsto k(\mathbf{w}, \mathbf{x}) + b$,

where the vector $\mathbf{w} \in \mathbb{R}^n$ and the scalar $b \in \mathbb{R}$ are built using the training set S .

Given a Hilbert space $\mathcal{H}$ defined by a kernel k , there exists a possibility that no affine hyperplane can separate the mapped data, in which case changing k might give a new Hilbert space $\mathcal{H}$ where such a separation is possible. Now, if the mapped data coming from a source of unknown distribution is separable by an affine hyperplane in $\mathcal{H}$, then there is a null probability that only one such hyperplane exists, that is, there is almost always an infinity of such affine hyperplanes. The question is which one shall be chosen? In the SVM theory, one chooses the unique affine hyperplane that maximizes the distance between itself and the nearest mapped data. Given an affine hyperplane H in $\mathcal{H}$ with a nonzero normal vector $w \in \mathcal{H}$ and bias $b \in \mathbb{R}$, the distance between a point $x \in \mathcal{H}$ and H is $\delta(x, w, b) = |\langle w, x \rangle_{\mathcal{H}} + b| / \|w\|_{\mathcal{H}}$. Now, supposing that x^* is the mapped data nearest to H , we have $\delta(x^*, w, b) = \delta(x^*, \lambda w, \lambda b)$ for all scalar $\lambda \neq 0$. By imposing the *convention* that $|\langle w, x^* \rangle_{\mathcal{H}} + b| = 1$, the *unique* normal vector of the *optimal* affine hyperplane is found by minimizing the quantity $\|w\|_{\mathcal{H}}$ subject to the constraints that the mapped data are separated. Data separation is enforced by the set of constraints $y_i g(\mathbf{x}_i) > 0$ for all $i \in [1, m]$, although SVM theory chooses the *convention* that $y_i g(\mathbf{x}_i) \geq 1$, for all $i \in [1, m]$.

In all the following, the dot product in $\mathcal{H}$ and its corresponding norm are denoted by $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$, respectively. The map from $\mathbb{R}^n$ to $\mathcal{H}$ that is implied by the choice of a specific kernel k is denoted by ϕ .

Hard-Margin Support Vector Machines

The (primal) optimization problem for the so-called hard-margin SVMs is

$$\min_{w, b} \left\{ \|w\|^2 / 2 : y_i (\langle w, \phi(\mathbf{x}_i) \rangle + b) \geq 1, \forall i \in [1, m] \right\}.$$

Note that a feasible solution exists only if the data are separable by an affine hyperplane in $\mathcal{H}$. Introducing real positive Lagrange multipliers $u_1, \dots, u_m$, the Lagrangian for this problem is given by $L(w, b) = \|w\|^2 / 2 + \sum_{i=1}^m u_i (1 - y_i (\langle w, \phi(\mathbf{x}_i) \rangle + b))$. It follows that the Karush–Kuhn–Tucker

(KKT) conditions at optimality for this problem are

$$\begin{cases} \nabla L(w, b) = \mathbf{0}, \\ u_i(1 - y_i(\langle w, \phi(\mathbf{x}_i) \rangle + b)) = 0, \forall i \in [1, m]. \\ u_1, \dots, u_m \geq 0. \end{cases}$$

From the second condition, we immediately deduce that, at optimality, $u_i = 0$ or $u_i \neq 0$ and $y_i(\langle w, \phi(\mathbf{x}_i) \rangle + b) = 1$. The training vectors $\mathbf{x}_1, \dots, \mathbf{x}_m$ such that $u_i > 0$ are called *support vectors* and hence the name support vector machine. From the first KKT condition, we obtain $w = \sum_{i=1}^m u_i y_i \phi(\mathbf{x}_i)$ and $\langle \mathbf{u}, \mathbf{y} \rangle = 0$ with $\langle \cdot, \cdot \rangle$ being the Euclidean dot product [3]. When these two equalities are substituted into the Lagrangian, we obtain $L(\mathbf{u}) = \langle \mathbf{1}_m, \mathbf{u} \rangle - \mathbf{u}^T \mathbf{Q} \mathbf{u} / 2$, where $\mathbf{1}_m$ is the m -vector made of 1s and $\mathbf{Q}$ is the matrix whose (i, j) -th element is $\mathbf{Q}_{ij} = y_i y_j k(\mathbf{x}_i, \mathbf{x}_j)$. We then derive a dual formulation for the hard-margin SVM, which is, in fact, the canonical SVM problem

$$\min_{\mathbf{u} \in \mathbb{R}^m} \left\{ \mathbf{u}^T \mathbf{Q} \mathbf{u} / 2 - \langle \mathbf{1}_m, \mathbf{u} \rangle : \langle \mathbf{u}, \mathbf{y} \rangle = 0, \mathbf{u} \geq 0 \right\}.$$

Let $I_+ = \{i \in [1, m] : u_i > 0\}$, then, for an optimal solution $\mathbf{u}$, the function g is given by $g(\mathbf{x}) = \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}) + b$. The bias b is obtained from the second KKT condition by $b = y_j - \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}_j)$ for any $j \in I_+$.

Soft-Margin Support Vector Machines

When a feasible solution does not exist for the hard-margin SVMs, then the training set is not separable by an affine hyperplane. To enable a few outliers to exist while computing the separating hyperplane, a set of m nonnegative slack variables $v_1, \dots, v_m$ is introduced into the constraints of the primal problem, giving $y_i g(\mathbf{x}_i) \geq 1 - v_i$ for all $i \in [1, m]$. The form of these constraints is a *convention*. If there is no constraint on the sign of the slack variables, then one can choose equality constraints $y_i g(\mathbf{x}_i) = 1 + v_i$ for all $i \in [1, m]$ or any variant instead of the classical inequality constraints above. Soft-margin SVMs traditionally pick up the set of inequality constraints and therefore obtain a multiobjective optimization problem in which one has to maximize the margin

while minimizing a p -norm of the slack vector. To avoid dealing with such a difficult optimization problem, the two objectives are summed with one objective weighted by a trade-off coefficient $C > 0$.

The objective function is $\|\mathbf{w}\|^2/2 + C\|\mathbf{v}\|_p$ with $v_i \geq 0$ for all $i \in [1, m]$. When $p = 1$, we have the primal optimization problem of L_1 soft-margin SVM and we obtain the following dual quadratic programming problem

$$\min_{\mathbf{u} \in \mathbb{R}^m} \left\{ \mathbf{u}^T \mathbf{Q} \mathbf{u} / 2 - \langle \mathbf{1}_m, \mathbf{u} \rangle : \langle \mathbf{u}, \mathbf{y} \rangle = 0, \right. \\ \left. 0 \leq \mathbf{u} \leq C \right\}.$$

The sole difference between the L_1 soft-margin SVM formulation and the hard-margin SVM formulation is the upper bound on the Lagrange multipliers $u_1, \dots, u_m$. Let $I_+ = \{i \in [1, m] : u_i > 0\}$; then, for an optimal solution $\mathbf{u}$, the function g is given by $g(\mathbf{x}) = \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}) + b$. Let $I_- = \{i \in I_+ : u_i < C\}$; then the bias b is computed by $b = y_j - \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}_j)$ for any $j \in I_-$.

When $p = 2$, the resulting dual formulation for the L_2 SVM is

$$\min_{\mathbf{u} \in \mathbb{R}^m} \left\{ \mathbf{u}^T \mathbf{H} \mathbf{u} / 2 - \langle \mathbf{1}_m, \mathbf{u} \rangle : \langle \mathbf{u}, \mathbf{y} \rangle = 0, \mathbf{u} \geq 0 \right\},$$

with $\mathbf{H} = \mathbf{Q} + 2\mathbf{I}_m/C$ and $\mathbf{I}_m$ is the $m \times m$ identity matrix. This formulation is almost identical to the one for hard-margin SVMs. Let $I_+ = \{i \in [1, m] : u_i > 0\}$; then, for an optimal solution $\mathbf{u}$, the function g is given by $g(\mathbf{x}) = \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}) + b$. The bias b is computed by $b = y_j - \sum_{i \in I_+} u_i y_i k(\mathbf{x}_i, \mathbf{x}_j)$ for any $j \in I_+$.

Kernels

There is a wide variety of kernels, blossoming various families of such functions, each one having desirable properties for certain kind of problems. Kernels can be chosen from a family or built specifically for one particular problem. In the latter case, one should keep in mind that kernels represent a measure of distance and angle into some (possibly higher dimensional) Hilbert space. The considerations related to what constitutes the “closeness” of two distinct observations is

left to the person modeling the classification problem and the nature of the manipulated data. The most commonly used kernels over $\mathbb{R}^n \times \mathbb{R}^n$ are as follows:

- $k(\mathbf{x}, \mathbf{y}) = \mathbf{x}^T \mathbf{Q} \mathbf{y}$ with $\mathbf{Q}$ being a symmetric positive semi-definite $n \times n$ -matrix. In particular, if $\mathbf{Q} = \mathbf{I}_n$, then $k(\mathbf{x}, \mathbf{y}) = \langle \mathbf{x}, \mathbf{y} \rangle$ (Euclidean dot product).
- $k(\mathbf{x}, \mathbf{y}) = (\mu + \langle \mathbf{x}, \mathbf{y} \rangle)^\nu$ with $\mu \geq 0$ and $\nu \in \mathbb{N}^*$ (polynomial kernels). The associated Hilbert space is the space of all functions $\mathbf{x} \mapsto x_1^{\nu_1} x_2^{\nu_2} \dots x_n^{\nu_n}$ such that $\sum_{i=1}^n \nu_i \leq \nu$, which is a space of dimension $\binom{n+\nu}{\nu}$ [3].
- $k(\mathbf{x}, \mathbf{y}) = \prod_{i=1}^n (1 + x_i y_i)$ (all-subsets kernels). The associated Hilbert space is the space of all functions $\mathbf{x} \mapsto x_1^{\nu_1} x_2^{\nu_2} \dots x_n^{\nu_n}$ such that $(\nu_1, \dots, \nu_n) \in \{0, 1\}^n$ [3].
- $k(\mathbf{x}, \mathbf{y}) = \sum_{1 \leq i_1 < \dots < i_\nu \leq n} \prod_{j=1}^\nu x_{i_j} y_{i_j}$ (ANOVA kernel of degree ν). The associated Hilbert space is the space of all functions $\mathbf{x} \mapsto x_1^{\nu_1} x_2^{\nu_2} \dots x_n^{\nu_n}$ such that $(\nu_1, \dots, \nu_n) \in \{0, 1\}^n$ and $\sum_{i=1}^n \nu_i = \nu$, which is a space of dimension $\binom{n}{\nu}$. A more general and flexible family of such kernels can be constructed from the so-called *graph kernel* [3].
- $k(\mathbf{x}, \mathbf{y}) = \exp(-\mu(\mathbf{x} - \mathbf{y})^T \mathbf{Q}(\mathbf{x} - \mathbf{y}))$ with $\mu > 0$; $\mathbf{Q}$ being a symmetric positive semidefinite $n \times n$ -matrix (generalized radial basis function kernels). These are the most widely used kernels, even though they are not robust to outliers [34]. The associated map $\mathbf{x} \mapsto k(\mathbf{x}, \cdot)$ has images into an infinite-dimensional Hilbert space [11].

Kernels exist for sets and structured data such as sequences and graphs [3]. They can be also built from other kernels or simply from a real-valued function f on the set that the observations belong to. If $\lambda \in \mathbb{R}_+$ and k_1 and k_2 are two kernels, then $k_1 + \lambda k_2$, $k_1 k_2$ (Schur product) and $(\mathbf{x}, \mathbf{y}) \mapsto f(\mathbf{x})f(\mathbf{y})$ are kernels. If p is a polynomial with positive coefficients, then $p(k)$ and $\exp(k)$ are also kernels.

Model Selection

Selecting a suitable kernel and an appropriate trade-off parameter C ensures the optimality of a binary classifier. However, this model selection is far from being straightforward but tools exist to help choosing effective models.

Cross-Validation. In a cross-validation, the training set S is *partitioned* into several subsets, which are alternatively used to build a classifier to be tested on the remaining subsets. In other words, the set S is iteratively divided into an actual training set, for which a classifier is built, and a validation set, for which the classifier is tested. At each iteration of the cross-validation, a *confusion matrix* $\mathbf{C}$ is constructed for the results of the validation set. For an ℓ -class problem, the matrix $\mathbf{C}$ is an $\ell \times \ell$ matrix for which each i -th row represents the number of samples belonging to class i and each j -th column represents the number of samples predicted to belong to class j . A measure of error on $\mathbf{C}$ is then devised in order to estimate the goodness of the chosen model. One such measure is $\varepsilon = \min_{i \in \ell} \{C_{ii} / (\mathbf{1}_\ell, \mathbf{C}_i)\}$ with $\mathbf{C}_i$ being the i th row of the matrix $\mathbf{C}$. In other words, this measure of error is the minimum fraction of correctly classified samples.

The repeated partition of S may be chosen randomly, although some samples might never be used for training or testing. Consequently, better cross-validation methods have been implemented and the most widely used ones are the l -fold cross-validation and its particular case, the leave-one-out (LOO) cross-validation. In an l -fold cross-validation, or more exactly in a *stratified* l -fold cross-validation, the set S is partitioned into k subsets of equal size that contains the same proportion of class labels as in S . During each iteration of the method, $l - 1$ subsets are used for training and the remaining subset is used for testing. Every subset is used for testing only once and hence a maximum of l iterations. At each iteration, the error ε can be seen as the result of a *Bernoulli trial* and its confidence interval can be easily calculated. The LOO cross-validation is an extreme case of the l -fold cross-validation in which only a single sample is taken out at each iteration

to be in the validation set. This last approach usually needs modifications in order to be efficiently implemented for large data sets.

Bootstrapping. Bootstrapping is a resampling technique for inferring sample statistics by drawing randomly with replacement several observations and testing them multiple times. An estimate of the distribution of the statistic is then obtained, which gives the possibility to validate different models.

Given a testing set of m observations and an SVM classifier, the following procedure is repeated l times (l is the number of rounds):

1. Sample n observations with replacement from the testing set.
2. Test the sample with the SVM.
3. Calculate and store a measure of error for the sample.

Once the procedure is finished, it is then possible to use the sampling distribution of the measures of error to estimate the median value and a confidence interval.

Pattern Search. If a finite number of kernels are available for a given problem, then cross-validation or bootstrapping schemes can be combined with a pattern search in order to isolate the best kernel and its best parameters, notably the trade-off parameter C . The objective is to minimize the measure of error returned by the cross-validations over the search domain. Nevertheless, this problem is no longer necessarily a convex optimization problem and deterministic pattern searches for convex problems are no longer guaranteed to successfully reach an optimal solution. Therefore, metaheuristics such as genetic algorithms, simulated annealing, tabu search, or ant colony optimization might be more suitable to minimize this objective.

Decomposition Techniques for Training SVMs

As highlighted in the previous sections, obtaining an SVM classification rule requires solving a quadratic programming problem. However, solving such problems on large data sets turns out to be a serious computational challenge. To circumvent this computational problem, Osuna *et al.* [35] were among the

first to introduce a decomposition technique, which was proved to be asymptotically convergent [36]. The outline of the decomposition method is as follows:

1. *Initialization* Set $i = 1$ and $q \in [2, m]$. Set $\mathbf{u}_1$ as initial solution of the SVM quadratic programming problem. Go to step 2.
2. If $\mathbf{u}_i$ is an optimal solution of the SVM problem then stop; otherwise, go to step 3.
3. Partition $[1, m]$ into two subsets S_1 and S_2 such that $|S_1| = q$. Let $\mathbf{v}_i$ and $\mathbf{w}_i$ be the subvectors of $\mathbf{u}_i$ corresponding to S_1 and S_2 respectively. Go to step 4.
4. Solve the L_1 soft-margin SVM programming problem for $\mathbf{v}_i$:

$$\min_{\mathbf{v}_i \in \mathbb{R}^q} \left\{ \frac{\mathbf{v}_i^T \mathbf{Q}_{11} \mathbf{v}_i}{2} - \langle \mathbf{1}_q - \mathbf{Q}_{12} \mathbf{w}_i, \mathbf{v}_i \rangle : \right. \\ \left. \langle \mathbf{y}, \mathbf{u}_i \rangle = 0, 0 \leq \mathbf{v}_i \leq \mathbf{C} \right\},$$

with $\mathbf{Q}_{\alpha\beta}$ being the submatrix of the matrix $\mathbf{Q}$ corresponding to the rows in S_α and the columns in S_β . Go to step 5.

5. Let $\mathbf{v}_{i+1}$ be the optimal solution of the problem in step 4. Set $\mathbf{w}_{i+1} = \mathbf{w}_i$; then $i \leftarrow i + 1$. Go to step 2.

Several partitioning methods have been proposed to obtain the subset S_1 . Osuna *et al.* [35] and Saunders *et al.* [37] cast observations that violate the KKT conditions into S_1 . In the sequential minimal optimization (SMO) method, Platt [38] imposes $q = 2$ so that the resulting quadratic optimization problem can be solved analytically. However, it also results that the choice of the elements of the subset S_1 is based on some heuristics. In the implementation of SVM^{light} [39], Joachims modifies the problem of step 4 and sets q to be an even number. A linear programming problem is derived so that the decision variable picks up the elements to be casted into S_1 [36].

MULTICLASS CLASSIFICATION SCHEMES

Two different family of approaches have been devised in order to deal with multiple-class

classification problems. The first family contains techniques that modify the structure of the basic SVM optimization problems in order to directly support and discriminate several classes. The all-at-once SVMs of Crammer and Singer [40] are designed in such a manner. The other family of approaches is more general in nature since the resulting multiclass classification schemes work with any type of binary classifier and not just with SVM binary classifiers alone. Vapnik proposed the one-against-all SVM [8], Platt *et al.* introduced a decision-tree-based scheme for multiclass classification [41], and Allwein *et al.* presented the use of error-correcting output codes for ℓ -class problems [42].

All-at-Once Support Vector Machines

In this framework [40], given an ℓ -class problem ($\ell \geq 2$), an observation $\mathbf{x} \in \mathbb{R}^n$ will belong to class $i \in [1, \ell]$ if $g_i(\mathbf{x}) > g_j(\mathbf{x})$ for all $j \in [1, \ell]$ such that $j \neq i$. The objective function for the primal problem is derived from the binary soft-margin SVM classifier. Assuming that $g_j(\mathbf{x}) = \langle \mathbf{w}_j, \phi(\mathbf{x}) \rangle$, then the objective function is $\sum_{j=1}^{\ell} \|\mathbf{w}_j\|^2/2 + C\|\mathbf{v}\|_1$ with $\mathbf{v} \geq \mathbf{0}$. The constraints are $(\mathbf{w}_{y_i} - \mathbf{w}_j)^T \phi(\mathbf{x}_i) \geq 1 - \delta_{y_i}^j - v_i$ for all $(i, j) \in [1, m] \times [1, \ell]$ with $\delta_{y_i}^j$ being the Kronecker symbol, that is, $\delta_{y_i}^j = 1$ if $j = y_i$ and 0 otherwise. The corresponding dual problem [43] is

$$\begin{aligned} \min_{\mathbf{u} \in \mathbb{R}^{m \times \ell}} \quad & \frac{1}{2} \mathbf{u}^T \mathbf{H} \mathbf{u} - \langle \mathbf{e}, \mathbf{u} \rangle \\ \text{subject to} \quad & \begin{cases} \langle \mathbf{1}_\ell, \mathbf{u}_i \rangle = 0, i \in [1, m], \\ 0 \leq (\mathbf{u}_i)_j \leq C \delta_{y_i}^j, (i, j) \in [1, m] \times [1, \ell]. \end{cases} \end{aligned}$$

The matrix $\mathbf{H}$ is defined by $\mathbf{H} = \mathbf{K} \otimes \mathbf{I}_\ell$ with $\otimes$ being the Kronecker product. The (i, j) th element of the matrix $\mathbf{K}$ is $\mathbf{K}_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ for all $(i, j) \in [1, m]^2$. The vector $\mathbf{u} \in \mathbb{R}^{m \times \ell}$ is composed of all the vectors $\mathbf{u}_i \in \mathbb{R}^\ell$, $i \in [1, m]$, in the following manner: $\mathbf{u}^T = (\mathbf{u}_1^T, \dots, \mathbf{u}_m^T)^T$. Similarly, the vector $\mathbf{e}$ is composed of all the vectors $\mathbf{e}_i \in \mathbb{R}^\ell$, where j -th elements are defined by $(\mathbf{e}_i)_j = \delta_{y_i}^j - 1$. The decision rule is given by $f(\mathbf{x}) = \arg \max_{j \in [1, \ell]} \sum_{i=1}^m (\mathbf{u}_i)_j k(\mathbf{x}_i, \mathbf{x})$. Determining the class of $\mathbf{x} \in \mathbb{R}^n$ requires ℓ decision evaluations when the decision functions are

trained all at once on a problem that has $m \times \ell$ variables.

One-Against-All Support Vector Machines

A simple multiclass classification scheme for ℓ classes was proposed by Vapnik [8] for binary classifiers having a real-valued decision function g that is strictly positive if a point $\mathbf{x} \in \mathbb{R}^n$ belongs to the class it discriminates and negative if it does not. In this scheme, a total of ℓ binary classifiers are trained, each one of them determining whether a given observation belongs to one single class or not, that is, if it belongs to the rest of the classes or not and hence the name *one-against-all*. Suppose that ℓ such decision functions $g_1, \dots, g_\ell$ are determined, then the final classification rule f for determining the class of a given observation $\mathbf{x} \in \mathbb{R}^n$ is $f(\mathbf{x}) = \arg \max_{i \in [1, \ell]} g_i(\mathbf{x})$. Like for the all-at-once SVM, determining the class of $\mathbf{x}$ requires ℓ decision evaluations but each decision function g_i is trained on $m = \sum_{i=1}^{\ell} m_i$ observations, m_i being the number of training observations belonging to class i .

Decision-Tree-Based Support Vector Machines

Platt *et al.* [41] introduced a decision-tree-based architecture for binary classifiers returning Boolean values. This architecture is the one of a *decision-directed acyclic graph* (DDAG) that is, as the name suggests, a scheme based on a directed graph with no cycles. Suppose that, for a ℓ -class classification problem, a total of $\ell(\ell - 1)/2$ pairwise binary classifiers are trained, that is, we are given decision rules f_{ij} discriminating between class $i \in [1, \ell]$ and class $j \in [1, \ell]$ with $i < j$.

The DDAG classifier has a pyramidal structure in which every node but the root node has two direct successors, and every node but the leaf nodes has two direct predecessors. A path from the root node to one of the leafs is computed by updating an ordered list of classes to be tested, each node successively removing one element from that list. The removing process works by picking up the decision rule f_{ij} discriminating the class at the top of the list, denoted by i , from the one at the bottom, denoted by j ,

Figure 1. DDAG for a four-class problem. Each edge is labeled with the class number that has been removed from the list.

and testing whether the observation $\mathbf{x} \in \mathbb{R}^n$ belongs to class i or class j . If, for example, $\mathbf{x}$ belongs to class i , then the next node on the path would be the node which list does not contain j and reciprocally; hence, the reason for two direct successors at each node. The path starts at the root node with initial list $\{1, \dots, \ell\}$ and goes to one leaf node with a list containing only two classes. Once the leaf node has been reached, the last decision is made and the last class is removed from the list, the remaining one being the class $\mathbf{x}$ belongs to (Figure 1). Determining the class of $\mathbf{x}$ requires $\ell - 1$ decision evaluations and each decision function g_{ij} is trained on $m_i + m_j$ observations, m_i being the number of training observations belonging to class i and m_j being the number of training observations belonging to class j .

Error-Correcting Output Code SVMs

Suppose $l \geq 1$ Boolean decision functions $f_1, \dots, f_l$ are given for an ℓ -class problem. A function f_i , $i \in [1, l]$, will return either $+1$ or -1 depending on which class the input belongs to. If the function f_i was not trained to discriminate one class, then, by convention, the output will be zero for this class. An example is given in Table 1 where all outputs are arranged into a decision matrix.

Denoting an $\ell \times l$ decision matrix built from $f_1, \dots, f_l$ by $\mathbf{D}$, we can notice that each row of $\mathbf{D}$ represents a code that we seek to be unique for each class. If it is the case, then for an observation $\mathbf{x} \in \mathbb{R}^n$, the outputs for every f_i , $i \in [1, l]$, are put in order so it forms the code for $\mathbf{x}$, which is then stored

Table 1. Example of Error-Correcting Codes for a Four-Class Problem and Five Decision Functions

Class	f_1	f_2	f_3	f_4	f_5
1	0	-1	-1	-1	+1
2	+1	-1	0	+1	+1
3	+1	-1	-1	-1	0
4	-1	+1	+1	0	-1

in an $l \times 1$ vector $c(\mathbf{x})$. This code is then compared to each row of $\mathbf{D}$ by computing a distance between $c(\mathbf{x})$ and the codes on the rows of $\mathbf{D}$. The class of $\mathbf{x}$ will be the one with the minimum distance between $c(\mathbf{x})$ and the code on the row corresponding to that class. The distance proposed by Allwein *et al.* [42] between $\mathbf{x}$ and the i th class is $d(c(\mathbf{x}), \mathbf{D}_i) = \sum_{j=1}^l (1 - \text{sign}([c(\mathbf{x})]_j \mathbf{D}_{ij})) / 2$ and the final decision rule is $f(\mathbf{x}) = \arg \min_{i \in [1, \ell]} d(c(\mathbf{x}), \mathbf{D}_i)$. This approach is, in a way, a generalization of the one-against-all technique and the decision-tree-based technique for which a potentially lesser number of decision functions is needed in order to determine classes. Furthermore, depending on the codes contained in $\mathbf{D}$, the size of the programming problems to be solved can be significantly reduced. The contents of $\mathbf{D}$ also suggest that there exists optimal codes that combine a high discriminating power and a short number of decision functions trained on smaller problems.

MACHINES BASED ON CENTRAL REPRESENTATIONS OF THE VERSION SPACE

More recent approaches consider the concept of the center of a convex set together with general nonlinear programming techniques. They aim at improving the generalization performances over standard SVMs and at creating *sparse hypotheses*. The interpretation of these approaches is based on the observation that the dual of the data points in the input space become hyperplanes and separating hyperplanes become points reciprocally. From a Bayesian point of view, an SVM solution can be viewed as the center of the *largest hypersphere* that can be inscribed in the set of

Figure 2. Example of a version space in $\mathbb{R}^3$. The version space is the surface segment of the hypersphere shown here restricted by hyperplanes in which consistent hypotheses can lie. Each hyperplane corresponds to a labeled training instance.

all consistent *hypotheses* called the *version space* (Figure 2). The version space boundaries are tangentially touched by the inscribed hypersphere, the support vectors corresponding to samples with hyperplanes touching the hypersphere [44,45]. Mathematically, given a training set $S = \{(\mathbf{x}_i, y_i) \in \mathbb{R}^n \times \{-1, 1\} : i \in [1, m]\}$ of m observations and a map $\phi : \mathbb{R}^n \mapsto \mathcal{H}$ to the feature space $\mathcal{H}$, the version space $\mathcal{V}$ is defined as $\mathcal{V} = \{w \in \mathcal{H} : \|w\| = 1, y_i \langle w, \phi(\mathbf{x}_i) \rangle \geq 0, i \in [1, m]\}$.

Bayes Point Machines

If a version space is asymmetric or elongated, then the center of the largest inscribed hypersphere does not appear to be the best choice. An alternative approach with a potentially better generalization performance is to find an optimal solution using the Bayes point approximated by the center of mass of the version space. However, calculating this center requires the computation of the version space volume, which is a #P-hard problem [46]. Several methods have been proposed

to approximate the center of mass of the version space. *Bayes point machines* (BPMs) developed by Herbrich *et al.* [44], Ruján [47], and Minka [48] estimate the Bayes point or the center of mass by averaging over weight vectors drawn according to the uniform posterior distribution. BPMs construct a hypothesis based on this center of the version space and this choice can be justified by theoretical arguments [49,50] in addition to having a geometric appeal. Given a training set $S = \{(\mathbf{x}_i, y_i) \in \mathbb{R}^n \times \{-1, 1\} : i \in [1, m]\}$ of m observations, a map $\phi : \mathbb{R}^n \mapsto \mathcal{H}$ to the feature space $\mathcal{H}$ and a decision rule $f(\mathbf{x}) = \text{sign}(\langle w, \phi(\mathbf{x}) \rangle)$, the Bayes classification strategy is given by

$$\begin{aligned} f_{\text{Bayes}}(\mathbf{x}) &= \text{sign} \left(\int_{\mathcal{V}} f(\mathbf{x}) p(w|S) dw \right) \\ &= \text{sign} \left(\int_{\mathcal{V}} \text{sign}(\langle w, \phi(\mathbf{x}) \rangle) p(w|S) dw \right) \\ &\approx \text{sign} \left(\text{sign} \int_{\mathcal{V}} \langle w, \phi(\mathbf{x}) \rangle p(w|S) dw \right) \\ &= \text{sign} \left(\left\langle \int_{\mathcal{V}} w p(w|S) dw, \phi(\mathbf{x}) \right\rangle \right), \end{aligned}$$

where $p(w|S)$ is the probability of the weight vector w given the training set S . The center of mass is $w_{\text{CM}} = \int_{\mathcal{V}} w p(w|S) dw$ and therefore the Bayes point can be approximated by the center of mass under the uniform posterior distribution condition that is, $w_{\text{Bayes}} \approx w_{\text{CM}}$.

In one approach [47], the center of mass is determined using a kernelized billiard algorithm in which the version space is traversed uniformly and an estimate of the center of mass is repeatedly updated. Informally, the center of mass is estimated by averaging over the trajectory of a billiard ball bouncing in version space. In another approach, the perceptron algorithm is used to obtain a large number of classifiers in the version space by learning on different permutations of the training set. Then, the Bayes point is approximated using the average of the weight vectors of those classifiers. Their results showed that BPMs have better generalization performances compared to SVMs in the hard

boundary or hard-margin case, but the performance improvement over SVMs in the soft boundary case is decreased.

Relevance Vector Machines

For a large majority of data sets, the version space diverges from sphericity and a BPM outperforms an SVM at statistically significant levels. For artificial examples with very elongated version spaces, the generalization error of a BPM can be half that of an SVM [44,51]. However, current implementations of BPMs have a number of drawbacks: the algorithm can be slow in execution and better mechanisms for a soft boundary (an imitation of a soft margin) need to be found. The BPM may exhibit good generalization performances, but it has the disadvantage that the hypothesis is dense that is, nearly all data points appear in the final hypothesis. Ideally, we would also like to derive kernel classifiers that give sparse hypotheses using a minimal number of data points. The most effective means of obtaining sparse hypotheses remains the object of research, but an excellent approach is the *relevance vector machine* (RVM) of Tipping [52]. The RVM formulation utilizes a probabilistic Bayesian learning framework in order to obtain sparse solutions and provide probabilistic outputs. Other advantages of RVMs are automatic estimation of parameters and the ability to use arbitrary basis functions. The results showed that performance of RVMs is comparable to SVMs in terms of generalization.

Analytic Center Machines

Rather than using the center of mass of version space, an alternative might be to use a hypothesis that lies toward the center of this space but which is much easier to compute. Such an example is the *analytic center machine* (ACM) (Fig. 3).

On the basis of the utilization of the analytic center of the version space, Trafalis and Malyscheff [45] proposed ACMs for binary classification. Their experimental results indicated that the ACM also outperforms SVMs in the hard boundary case. The ACM uses a logarithmic barrier function whose value on a point grows to infinity as the point approaches the boundary of the version space. The analytic center of the version space is then determined when this function achieves its minimum and can be written as

$$w_{\text{ACM}} := \arg \min_{w \in \mathcal{V}} \left\{ - \sum_{i=1}^m \ln(y_i \langle w, \phi(\mathbf{x}_i) \rangle + b) \right\}.$$

Suppose we are given a kernel $k(\mathbf{x}_i, \mathbf{x}_j) = \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle$ and $\mathbf{w} = \sum_{i=1}^m u_i \phi(\mathbf{x}_i) + v$, the ACM formulation can be defined in the space of $(\mathbf{u}, v) \in \mathbb{R}^{m+1}$ as

$$\min_{(\mathbf{u}, v) \in \mathbb{R}^{m+1}} \left\{ - \sum_{i=1}^m \ln(\langle \mathbf{u}, y_i \mathbf{K}_i \rangle + y_i v) : \|\langle \mathbf{u}, v \rangle\|^2 = 1 \right\},$$

where $\mathbf{K}$ is the kernel matrix which (i, j) -th element is $\mathbf{K}_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ for all $(i, j) \in [1, m]^2$. Trafalis and Malyscheff solved this optimization problem using a projected Newton descent method and proposed an online

Figure 3. The analytic center of version space (w_{ACM}) and the center of the largest inscribed sphere (w_{SVM}) in an elongated version space.

approach in the implementation of ACM. They also suggested that a better classification performance can be achieved by removing redundant constraints that are not essential for the description of the version space.

p-Center Machines

Another approach proposed by Brückner [53] is based on an approximation of the *p*-center of the version space, the so-called *p*-center machine (*p*-CM). In the *p*-CM formulation, Brückner utilizes the *p*-center, which was initially proposed by Moretti [54] who introduced an efficient iterative algorithm to find the center of a polytope using a weighted projection centering method. Moretti showed that the *p*-center can be achieved in polynomial time and that the algorithm is parallelizable so that the computational effort can be improved significantly. Following this work, Brückner indicated that the *p*-center is also close to the Bayes point and that the *p*-CM has similar performances to SVMs and BPMs.

CONCLUSIONS

In this article we have provided a review of the theory of SVMs from the perspective of classification. Several modifications of SVMs, such as the ACM, the BPM, and the *p*-center machine, have been also discussed. In addition, kernel methods, model selection techniques, and computational issues have been investigated. There were several approaches that have not been discussed such as classification problems with noisy data [29,55,56], SVMs clustering and regression, as well as incremental SVMs [57,58]. SVMs and kernel methods have been found to work well in practice; however, the subject is still very much under development, but it can be expected to develop an important tool for data mining, machine learning, and their many applications.

SUPPORTING THE STRATEGY PROCESS: THE ROLE OF OPERATIONAL RESEARCH/ MANAGEMENT SCIENCE

FRANCES O'BRIEN
Warwick Business School,
University of Warwick,
Coventry, UK

INTRODUCTION

To explore how operational research/management science (OR/MS) can support the strategy process, it is helpful first to define what is meant by the terms strategy and strategy process. However, defining the term “strategy” is not as simple as it may seem. As De Wit and Meyer note, “. . . a common definition of the term strategy is illusive,” because there are “. . . strongly differing opinions on most key issues and disagreements run deep. . .” [1, p. 3]. The traditional view is that strategy is something an organization *has* [2], consisting of “. . . the direction and scope of an organization over the long term, which achieves advantage in a changing environment through its configuration of resources and competences with the aim of fulfilling stakeholder expectations.” [3, p. 9]. Implicit within this definition is the notion of strategic decisions that need to be made within the organization and external issues that the organization may have to face.

Every organization faces issues and decisions that are of strategic importance; examples of strategic decisions abound in every sector at every level: a retailer may wish to consider a decision to move into new markets or offer new product ranges; a manufacturer, facing decreasing demand for their products, may be forced to reduce production and to close factories. Strategic decisions have a number of characteristics. For example, Coyne and Subramanian [4] describe strategic decisions as those which

- drive or shape most of a company's subsequent actions;
- are not easily changed once made;
- have the greatest impact on whether the company's strategic objectives are met.

Pidd [5] adds to this by noting that since strategic decision making is crucial to an organization's survival, the “temperature of the debate can be very high” and that there may be considerable confusion over the objectives. He also notes that strategic decisions are often complex, involving many different interacting factors that have to be dealt with by individuals who may each see things differently. Dyson [6] notes that strategic decisions require investment of significant resources, and often involve a delay between their implementation and realization of results. In addition, Kirkwood [7] points out that it is often difficult retrospectively to determine whether an option chosen was the right one.

Organizations also face issues that are of strategic importance and where the need to make a decision is not immediately obvious, until some further understanding of the issue and its impact on the organization is gained. Consider the following example. As a result of the recent turmoil in the financial markets, a national government is considering revising the regulatory system for their financial services sector. For an organization operating in such a sector, the impact of such an environmental change may not be immediately obvious. Managers would want to understand the nature of the issues involved and how they might impact on their business both in the immediate here and now and over the longer term. An analysis of the issues may lead managers to review and revise the organization's direction, which in turn could lead to a review of its current decisions and policies and the development and evaluation of new ideas. The activities relevant to this example are those of making sense of issues, setting direction, and revising existing or developing and evaluating new strategic options. Such

activities can be connected into a process of interrelated activities that together bring about the strategic development of an organization.

Processes that facilitate the development of strategy within organizations can be differentiated by the extent to which they are deliberate or emergent. Johnson *et al.* [3] describe deliberate or intended strategy processes as those including strategic planning activities, strategy workshops, and the use of external consultants, each of which are designed to proactively explore issues and develop strategic ideas and recommendations prior to their implementation. In contrast, they describe emergent strategy processes as including experimentation and learning from partial commitments (logical incrementalism), resource allocation routines, cultural processes, and organizational politics. Under this view, strategy is not something that is planned; rather, it is something which emerges over time. A number of authors [3,8,9] note that it is helpful to see strategy as a blend of both the intended and the emergent; indeed, Hart and Banbury suggest that adopting multiple strategy processes improves organizational performance [8]. This review is primarily situated with the intended or planned view of strategy in that it describes a process for intentionally developing strategy through a set of interrelated activities and identifies tools that can be used to support such activities. However, it is important to remember that the debates involved within an activity revolve around people who may have strongly held views. Thus, in practice, supporting the strategy process at times exhibits emergent characteristics.

This article focuses on how the process of developing strategy within organizations can be supported with approaches from both the OR/MS and other fields. It begins by introducing a number of key activities that together form the strategy process. Next, it considers the issue of how the strategy process may be supported by reviewing the literature covering the use of approaches to support strategy. Using this literature, the article explains how a variety of approaches can be brought together and mapped onto the elements of

the strategy process as support mechanisms. Finally, a number of suggestions are made regarding future research directions relevant to this field.

STRATEGIC DEVELOPMENT PROCESSES

Just as there are many different definitions of strategy, there are also numerous versions of the strategy process [1,3,9]. For this article, the strategic development process originating from Dyson and Foster's empirical research [10,11] has been chosen since it contains many of the activities found in other strategy processes, but more importantly because it promotes the importance of strategy rehearsal, prior to implementation—a feature that sits comfortably within the ethos of the OR/MS discipline. At its core are a number of activities which Dyson and Foster suggest are “essential” for effective strategy development [10,11]. The following list of activities has been taken from more recent theoretical research [12], which has evolved from this earlier work:

- Strategic direction (where are we heading?):
 - setting direction, including vision and mission;
 - setting objectives, priorities, goals, targets, and performance measures—all informed by and aligned with direction.
- Current and future strategic position (what are we facing, now and in the future?):
 - assessing the external environment (social, political, economic, competitive, technological, and regulatory issues);
 - assessing the internal environment (resources and capabilities).
- Strategic choices (how can we get there?):
 - generating ideas for strategic initiatives/options;
 - rehearsing and revising ideas in a virtual feedback process that incorporates learning from virtual or projected performance;

Figure 1. The strategic development process [12, Figure 1.7, p. 12].

- selecting initiatives/options.
- Making it happen (how are we progressing?):
 - learning from current organizational performance;
 - optimizing operational efficiency;
 - implementing strategic decisions/strategic change (i.e., enacting strategy).

Figure 1 [12, p.12] demonstrates how the activities listed above interrelate with one another and together form a strategy process. It is noticeable that the process is not linear but is framed around a closed, feedback loop, where the outcome of the process, learning from current performance, feeds back to influence both ongoing change and the direction-setting process. While the logical starting point from a conceptual perspective is the setting of direction, presenting the process as an interrelated system of activities

indicates that it does not have to be followed in a strictly linear fashion from one starting point. For example, managers may meet to consider how they may assess some issues in the external environment, which may lead them to reconsider the direction and initiatives of the organization.

Another feature of the process presented in Fig. 1 is the clear distinction made between rehearsing and enacting strategy, where the rehearsal of ideas and the examination of their consequences prior to implementation are seen as important aspects of the decision-making process. The figure shows that the rehearsal process itself is an iterative loop involving the use of a model or models, highlighting that a number of different modeling approaches can be used to help managers think through the consequences of their ideas.

SUPPORTING STRATEGIC DEVELOPMENT PROCESSES

A natural place to look for approaches to support the strategy process would be some of the mainstream strategy textbooks. A cursory glance of such textbooks [3,9,13] would reveal a number of classic approaches including PEST analysis (political, economic, social, technological) for exploring the organization's external environment, Porter's five forces (threat of new entrants and substitutes, bargaining power of suppliers and buyers, and intensity of rivalry) for exploring competitive forces within an industry, and SWOT analysis (strengths, weaknesses, opportunities, and threats) for exploring the organization and its environment, amongst others. One notable feature of such approaches is that individually they do not support the whole process; rather, they provide a particular perspective for part of the process or a specific activity. Thus, it is quite usual to find multiple tools being brought together to offer insights from different perspectives and levels. Another noticeable feature is that the reader is unlikely to find many approaches familiar to the OR/MS practitioner, apart from scenario planning, a tool for exploring future uncertainty in the external environment. This is not to say that the OR/MS has little to offer strategy support as the following paragraphs demonstrate.

Historically, OR/MS has been concerned with supporting decision makers through the use of "...appropriate analytical methods..." [14]. OR/MS approaches are characterized by their rational and systematic nature. Pidd [5] distinguishes between two forms of rationality and thus the nature of support that approaches can provide to strategy development: substantive rationality (rational choice) and procedural rationality (process of rational choosing). As he explains, "...substantive rationality is suited to situations in which the means to an end are uncertain, but the ends are known and the problem is finding some way to choose between these options." (p. 793) However, when the ends are not known or agreed upon and thus form the actual topic under consideration, procedural rationality

may be more helpful since it "...requires processes and tools that support the search for alternatives that encourage systematic information gathering and analysis and that help people find acceptable solutions when there is conflict." (p. 794)

Traditional OR/MS approaches, largely quantitative, typically belong to the realm of substantively rational approaches. Consider the work of Freeman who describes the use of a strategic simulation model "...the aim of which was to translate wide-ranging demands on the force into detailed operational staffing requirements." [15, p. 187]. Another example is the work of Vasko and Stott [16], who present the formulation of a linear programming (LP) model used to support the evaluation of a particular strategic option. Their work considered the issue of whether an idle facility should be opened in order to boost overall production capacity since it was believed that such an action might enable the organization to capture more of the existing market for the relevant products. In using such quantitative tools, the OR/MS practitioner is often in the role of expert modeler whose role is to undertake analysis of an issue or decision and provide interpretations and/or recommendations based on their analytical efforts. However, Eden [17] argues that strategy development would be more effective if seen as a "social process" rather than an analytical one, where the role for OR/MS is to provide facilitation, using appropriate tools, rather than to provide the actual analysis needed in a problem-solving mode. The development of problem structuring methods (PSMs) or soft OR approaches [18], evident over the past 20 years fits well with Eden's view. PSMs are largely qualitative approaches suited to problem situations characterized by

- "multiple actors,
- differing perspectives,
- partially conflicting interests,
- significant intangibles,
- perplexing uncertainties." [19].

Pidd [5] explains that "the soft approaches aim to provide decision support that is procedurally rational, although how they do this

varies...[They] all aim to help people to find enough accommodation to make progress on wicked problems without ignoring the realities of power and influence.” (p. 798) He gives the examples of soft systems methodology, which provides a combination of frameworks (CATWOE—customers, actors, transformation process, worldview, owner, environmental constraints) and approaches (rich pictures and activity modeling) to help people think through their different worldviews as well as SODA (strategic options development and analysis), using cognitive mapping, and SCA (the strategic choice approach), which both provide guidance on how to structure and manage the steps of an intervention.

Clearly, as there are a number of different activities within the strategy process, there are multiple possible roles for OR/MS in supporting strategy, since it is not possible to support the whole process with a single approach. Some aspects of the process can usefully be supported through the processes of group facilitation and negotiation, while others can be supported through the use of expert analysis that can be fed into the strategy process. Ormerod [20, p. 118] notes that the opportunities for OR/MS in supporting strategy are “multiple and varied” and may involve “...help with analysis or help with the process or both.” Dyson [6] advocates supporting the strategy process through the use of both OR/MS and tools from other fields, where the term “tool” “...is used as a generic name for any method, model, technique, tool, framework, methodology or approach used to provide decision support. Tool therefore refers to a decision aid used in a methodological manner for specific purposes in decision making or planning activities. A tool can be either quantitative or qualitative and can be manual or computerized. It can be based on OR/MS methods or methods from another discipline. A tool can also be based on one or several methods.” [21, p. 931].

Supporting the strategy process is one of three streams of endeavor that make up the OR and Strategy field [22], the other two streams being identified as strategic OR which Bell [23] defines as “Operations Research which achieves a sustainable competitive advantage” and public sector

policy analysis, attributed to Rosenhead [24], which considers issues and decisions such as public health planning [25], energy supply and planning [26,27], policy analysis for the prison service [28], privatization of a public enterprise [29], understanding social reforms [30], and modeling the impact of financial decisions for a government department [31].

A number of studies have been undertaken into the use of “tools” to support strategy [21,32–37]. These studies, reviewed in the next section, cover two sources of evidence: literature reviews covering articles describing the use of specific tools to support strategy and surveys of the practice of tool use.

Tools for Supporting Strategy: A Literature Review

Few articles exist that review the literature concerning tools to support strategy. Clark [32] provides a picture of the literature up to 1990 where his review explored the use of OR/MS tools to support strategic planning. He identified some 24 tools from the literature between 1980 and 1990 and mapped their use onto the relevant stage in the strategy process, which he organized into four stages: analyzing the environment, planning direction, planning strategy, and implementing strategy. He also noted whether the publication concerned application of a tool or theory development. Of the 766 papers classified, 75 were concerned with analyzing the environment, where forecasting was the most frequently used tool. Only three papers were concerned with planning direction, including the setting of mission and vision. Planning strategy was covered in 133 papers, 74 of which were concerned with evaluating strategy and where forecasting and simulation were the most popular tools. Implementation accounted for some 76 papers where forecasting, project management, and spreadsheets were the most popular tools. What is clear from Clark’s review is that the traditional or harder OR/MS approaches, such as simulation and forecasting, play a prominent role in the literature, whereas there were few articles reporting the use of “softer” approaches in supporting the four stages, and in particular the planning direction stage.

From 1990 onward, the volume of articles describing the use of particular tools to support strategy has increased; thus, if the literature review were repeated today, a rather different picture might emerge. To demonstrate this, Table 1 identifies a number of tools drawn from the OR/MS and other fields that have been documented as being used to support activities within the strategy process. In particular, Table 1 identifies each tool's source (OR/MS or strategy/management) and maps the tool onto the activities it can support. For the reader who may wish to further understand how a tool is used to support an activity, the table also identifies a selection of references that specifically describe the application of a tool in relation to one or more of the activities highlighted.

It is noticeable in Table 1 that the mapping between tools and activities in the process is not one-to-one; tools may be used to support multiple activities. For example, visioning approaches do not necessarily stop once the vision and direction have been defined; they may incorporate an assessment or exploration of the external and internal environments, or they may include the generation of initiatives that are needed to bring about the vision. Similarly, while scenario planning is primarily intended as a tool to explore possible future uncertainties within the external environment, it can also be used to help generate strategic initiatives and to test their robustness against plausible possible futures.

Tools for Supporting Strategy: Surveys of Practice

The literature surveying the use of tools to support strategy has investigated two practitioner groups—OR/MS practitioners and executives/MBA alumni. Table 2 summarizes the common tools that were found to be used across six surveys, four of which were conducted with executives or MBA alumni [21,34,35,37] and two of which were conducted with OR/MS practitioners [33,36]. For each of the four executive/MBA surveys, a rank was calculated indicating the extent of a tool's use amongst the respondents, with a rank of 1 indicating the tool used by the greatest proportion of respondents. However,

such a calculation was not possible for the two OR/MS surveys. Clark and Scott [33] identified the top tools for specific activities with no differentiation between their popularity. O'Brien [36] reported the regularity of tool use, thus the ranking of 1 associated with this survey indicates the tools reported as most regularly used to support strategic activities.

A few points are worth noting in Table 2. First there is no general agreement upon a definitive collection of tools that can be used to support strategy; each survey covers a different number and collection of tools, although there is some overlap as can be seen in the table; to facilitate this analysis, the table has been ordered according to the number of surveys a tool appears in, hence the first tool listed (balanced scorecard) appeared in five of the six surveys. One implication of the differences between toolsets is that there are a large number of tools included in the surveys that do not appear in Table 2, the reason being that they each were listed in only one survey; noticeable amongst this set is the top-ranked tool from Rigby and Bilodeau's survey [34], strategic planning, which is defined as "a comprehensive process for determining what a business should become and how it can best achieve that goal" [76]. Another feature of the differences between toolsets can be seen in the naming of tools. Take, for example, "resource-based view" and "resource capability analysis"; it is not clear whether these two tools are in fact the same or different. Second, with the exception of SWOT analysis, the rankings typically vary across the surveys. SWOT analysis does, however, stand out compared to the other tools since it was found to be the tool used by most respondents in three of the executive surveys and it was also reported as being used by OR/MS practitioners. Finally, the overall list of tools presented in the table spans both the OR/MS and the strategy fields, as can be seen by the column labeled "source," where "O" indicates a tool from the OR/MS field and "S" indicates a tool from the strategy or management field. A closer inspection of Table 2 reveals that the executive surveys largely cover strategy or management tools; only the surveys by

Tools in survey		22	25	19	15	18	52

Note: Tools are ranked according to the proportion of respondents reporting their use, with a rank of 1 indicating the tool most reported as used to support strategy. The Clark and Scott survey notes which were the top tools rather than ranking tools in any specific order. O'Brien's survey reports the regularity of use of a tool, hence the ranking applied to this survey reports the most regularly used tool with a rank of 1 being the tool reported as most regularly used to support strategy. Source of tool: S, strategy; O, OR/MS.

Tapinos [35] and Stenfors *et al.* [21] include a few of the OR/MS tools, notably statistical analysis, simulation, and optimization in the case of the former and cognitive mapping and soft systems methodology in the case of the latter. Similarly, the OR/MS survey by Clark and Scott [33] covers mostly OR/MS tools, while O'Brien's survey covers a spread of OR/MS and strategy tools. These two surveys shall now be considered in greater detail to illustrate the use of OR/MS and strategy tools by OR/MS practitioners.

Clark and Scott [33] conducted an empirical study into the strategic level OR/MS tool usage in the United Kingdom by practitioner members of the UK OR Society. Their survey related tool use to specific stages in a three-phase strategy process: phase one of the process involved a situation assessment (i.e., where are we now?); phase two concerned a strategic analysis (i.e., where are we going?), and phase three related to strategic implementation (i.e., how do we get there?).

The tools used to support phase one included simulation, spreadsheets, LP, forecasting, and financial models, all used to appraise the current internal environment. In addition, for setting objectives and mission brainstorming, Porter's five forces and soft systems methodology were used. For exploring the external environment, forecasting, spreadsheets, risk analysis, financial models, and statistical analysis were reported as being used. To support phase two, which involved generating, evaluating, and choosing between alternative strategic options, spreadsheets, simulation, LP, and cost-benefit analysis were used. Finally, to support phase three, activities such as developing implementation plans and monitoring and reviewing performance, project management, simulation, and statistical analysis were used. Clark and Scott concluded that OR/MS practitioners were involved with most of the core strategic tasks within an organization. It is noticeable that in the tools reported as being used, some appearance of the softer approaches was noted (e.g., soft system methodology); In addition, it is noticeable that OR/MS practitioners also reported the use of management

and strategy tools (e.g., Porter's five forces and brainstorming), particularly to support phase one of the process. In a viewpoint relating to Clark and Scott's paper, Pidd [77] queried the lack of soft OR in responses; the authors, in their response [78], suggested that the approaches were at that time still not widely known or used.

O'Brien's [36] survey into the practice of supporting strategy within the United Kingdom OR practitioner community follows Clark and Scott's [33] previous research in that it invited participants to identify the tools that were used to support strategy within their organization, and to relate these tools to specific activities within the strategy process described earlier in this article. The work also identified which tools were combined to support strategy. The survey found that a variety of tools was used to support strategy, including tools from both within and beyond the OR/MS field. Amongst the tools cited as most used to support strategy were financial analysis, project management, benchmarking, brainstorming, cost-benefit analysis, forecasting, risk analysis, and statistical analysis. It was also noticeable that strategy tools (e.g., SWOT analysis, Porter's five forces, and PEST analysis) were reported as being used along with OR/MS tools. In addition, the awareness of softer OR/MS or problem structuring methods was greater than their reported use might suggest. Tools were also reported as being used in combination to support strategy development; popular combinations included scenario planning with simulation and SWOT with PEST analysis. The activity that most tools were associated with was that of strategy evaluation, followed by performance measurement and assessment of the external environment, whereas the activities that tools were least associated with were setting direction, generating options, and implementing strategy. When tools were mapped onto specific activities, it was clear that the relationship between tools and activities was not a one-to-one mapping; the same tool was reported as being used to support more than one activity; for example, simulation was used to support evaluation and selection of options but some also reported its use for

assessing the environment and setting goals. Similarly, brainstorming was primarily used to generate options, set direction and goals, but it was also used to assess the internal and external environments.

In reflecting about the characteristics of the emerging toolset for supporting strategy, one might expect that practitioners would restrict their toolset to those associated with their background, discipline, or training, but this does not appear to be the case—OR/MS practitioners, while drawing on tools from their own field, also draw on tools from the strategy and management fields, just as executives and MBA alumni draw on the strategy tools such as those commonly taught in MBA programs, but also utilize tools from the OR/MS field. Thus, Dyson's view [6] that tools from a wider field than OR/MS can be used to support strategy seems to be supported in practice. Further research is needed into how tools are used to support strategy; surveys simply tell us that a tool is used to support an activity, but not how, when, or with whom? In particular, a topic for research is how tools are used by the OR/MS practitioner in relation to the decision makers, for the assumption is that the OR/MS practitioner plays a support role rather than being the decision maker *per se*.

Combining Tools to Support Strategy

As demonstrated above, tools are not used in isolation but can be combined in supporting strategy. Within the OR/MS field, there have been recent developments in the use of multimethodological approaches where tools are combined in support of interventions [79]. There has been little systematic research in this area with respect to strategy development; however, some examples exist to illustrate the potential. The extant literature may be broadly divided into two groups. The first group includes tools that have been combined in order to provide complementary insights to the issues under consideration by highlighting different perspectives. The second group consists of tools that are combined either to create a new tool or whose purpose is to extend or supplement an existing tool into new areas. An example of the former is Brady's [80] use of Porter's five forces with

soft systems methodology to provide complementary insights into the issues surrounding the future of an Irish road gritting facility. An example of the second group is the extension of scenario planning through the addition of multiple criteria decision analysis to evaluate strategic options that have been generated through the development and analysis of alternative scenarios [50,51,81]. Other examples that belong in this second group include Ormerod's articles that report the combination of a number of typically soft OR/MS tools to support information systems strategy development across a range of organizations [82–84].

O'Brien's survey [36] suggests that tools from both the OR/MS and strategy toolsets are combined to support strategy. For example, the most reported combination of two tools in the survey was scenario planning with simulation, followed by SWOT analysis with PEST analysis. As with the use of individual tools, further research is needed to explore how and why practitioners are combining tools to support strategy. Further research might also usefully explore how tools from across the two fields can be combined in supporting strategy.

CONCLUSIONS AND FURTHER RESEARCH

This review began by explaining the concepts of strategy, strategic decisions, and issues. It then introduced the idea of a strategy process consisting of a number of key interrelated activities, which are needed for the effective strategic development of an organization. In reflecting on the rational nature of the OR/MS discipline, two forms of rationality were identified: substantive rationality that has characterized much of the traditional "hard" OR/MS approaches, and procedural rationality that characterizes many of the newer "soft" OR/MS approaches. In supporting the strategy process, it was noted that both substantively and procedurally rational approaches can offer support to different activities within the process. The review then summarized the literature and empirical research highlighting which tools have been used to support the activities of

a strategy process, either individually or in combination.

A key conclusion of this review is that the strategy process can be supported by a wide variety of tools, where the mapping between tools and activities in the process is not one-to-one; different tools can be used to support more than one activity and individual activities can be supported by more than one tool. Thus, in supporting the strategy process it can be beneficial to use more than one tool, since different tools typically offer varied and often complementary perspectives. A related conclusion is that tools for supporting the strategy process can be drawn from both the OR/MS and strategy fields. This field offers many opportunities for further research, some of which are identified below.

Firstly reviews and overviews of the literature documenting the variety of tools to support different activities within the strategy process are lacking both within the OR/MS and strategy fields. In particular, Clark's [32] literature review of the early 1990s could be usefully updated to provide a current picture taking account of more recent developments. For example, within the OR/MS field it would be useful to explore the literature reporting the use of specific soft OR/MS approaches or PSMs to support strategy development.

Second, this review has summarized empirical research, which has identified the tools used to support strategy by both OR/MS practitioners and executives/MBA alumni. While there is a reasonable knowledge of the tools that are used within the United Kingdom and Europe amongst the OR/MS community, little is known about the use of tools to support strategy by OR/MS practitioners within the United States and other regions of the world.

Third, the existing research has largely identified which tools are used to support strategy. However, knowledge that a tool is used does not tell the whole story; it provides a starting point for further research to explore both how and why the tools are used and combined to support strategy within organizations. Issues that are relevant to this research include, for example, the extent to which tools are used as theory promotes,

or modified to suit the particular circumstances within an organization. As Gunn and Williams [37] suggest, questions such as how and why tools are used are more difficult to research than identifying which tools are used and thus they require different research approaches. Such research could usefully be conducted adopting a strategy as practice lens [85], taking the view that strategy is an activity, something that people *do*. Such a perspective would enable the microlevel exploration of OR/MS practitioners as strategic actors engaged in strategy work. In particular, it would facilitate research into the practice of using tools, for example, how scenario planning is used within an organization, along with the detail of what actually happens during its use and which different actors are involved, say in the workshops where it is used.

Finally, there is scope to explore both theoretical and practical developments in how tools from across the two fields of OR/MS and strategy can be brought together to support strategy.

These conclusions have important implications for academics and practitioners alike. For practitioners, it suggests the need to look beyond their traditional training for tools that are of practical use in supporting strategy. For academics, it offers numerous opportunities for exploring the use and development of tools, possibly in combinations that bridge the different fields.

SURGERY PLANNING AND SCHEDULING

S. AYCA ERDOGAN

BRIAN T. DENTON

Edward P. Fitts Department of Industrial
and Systems Engineering, North
Carolina State University, Raleigh,
North Carolina

In 2007, total health-care spending in the United States reached US \$2.3 trillion, and continues to rise at the fastest rate in US history. The design and implementation of better planning and scheduling systems is an important area to study in order to reduce high costs and improve access to services in the health-care system. Surgery scheduling, in particular, is an area with significant potential for realizing greater efficiencies. Poor scheduling prevents health-care providers from matching patient demand with available capacity, causing inefficient use of resources, decreased return on investment, and long waiting lists for patients. It has been estimated that surgery accounts for more than 40% of a hospital's total revenues and expenses. Recent studies indicate that resource utilization, overtime, and on-time start performance within surgical suites could be improved at most hospitals. These important performance measures are influenced in part by the surgery scheduling systems and policies that are used in practice.

Surgery scheduling systems impact a variety of expensive resources including operating rooms (ORs), the postanesthesia care unit (PACU), intensive care unit (ICU), hospital beds, equipment resources such as mobile diagnostic imaging devices, and human resources including surgeons, nurses, anesthesiologists, and other staff. The unpredictable nature of surgery results in uncertainty in the duration of surgery and patient recovery. This can be caused by many factors including the varying experience of surgeons and OR teams, the presence of residents or surgical fellows in

academic medical centers, or patient characteristics like age, weight, or unobservable physiological factors that only become known at the time of surgery. Unexpected *add-on cases* (urgent surgeries that arise on short notice), patient cancellations, and unanticipated staff or resource unavailability are additional sources of uncertainty that can create problems on the day of surgery.

Surgery scheduling is also difficult because there are a number of competing performance criteria. The efficiency and effectiveness of a surgery schedule may be judged differently depending on the individual's perspective. For instance, OR managers are often concerned with utilization of resources such as ORs, expensive equipment, and staff. Patients, on the other hand, are more concerned with waiting time.

In this article, we provide a general overview of the most important parts of the surgery delivery system that affects surgery scheduling. We focus on the surgical suite itself since it comprises the most expensive resources in the delivery of surgical care. We describe the most significant factors that complicate surgery scheduling, and characterize the types of uncertainty that affect scheduling. Our review focuses on the literature related to surgery scheduling that has appeared in both the operations research and the health-care literature. We particularly emphasize recent studies that consider new and important aspects of surgery scheduling systems. We provide a taxonomy of the literature based on the type of operations research methodology used. We also provide a small example to illustrate how OR methods can be used in surgery scheduling. Finally, we briefly discuss some open challenges and opportunities that exist for future research.

SURGERY SCHEDULING

Surgery may be performed on an *inpatient* or an *outpatient* basis. In the hospital outpatient setting, patients are admitted to the

hospital and leave the hospital on the same day of the surgery. In such cases the patient recovers at home. In the inpatient setting, patients either arrive on the day of surgery or they are assigned to a hospital bed ahead of the day of surgery. Inpatients stay in the hospital to recover for one or more days following surgery. Owing to increasing volume, many outpatient surgeries are now performed in ambulatory service centers (ASCs), which are distinct from hospitals (though often associated with a hospital). ASCs include an intake area, often several ORs, and a recovery area. Unlike hospitals, ASCs are not equipped for emergencies or overnight stays and most of them are open 8–10 h a day.

The overall surgery process involves several activities before, during, and after the actual surgical procedure. These include *preoperative*, *intraoperative*, and *postoperative* stages. Figure 1 illustrates these stages as well as the related activities. Preoperative care starts with the patient's and surgeon's decision to have surgery. It may involve a visit to a preoperative clinic where an examination and follow-up tests may be completed. It also typically involves some preparation prior to the day of surgery. On the day of surgery, the patient arrives at the hospital or ASC at a preassigned time. A number of administrative activities may be required,

and the patient may require a brief physical examination or medical tests (e.g., blood test) before surgery. Intraoperative care comprises the activities performed in the OR. After surgery, the postoperative stage begins and patients are admitted to a recovery area such as a PACU or ICU depending on the nature of the surgery. In the case of inpatient surgery, the patients may return directly to their hospital bed. The complete surgery process ends when a patient has fully recovered and no additional follow-up is needed by the surgeon. This may take weeks, months, or even years. In this review, we focus on activities performed in the surgical suite on the day of surgery. Owing to the high cost of surgical suite resources, this is often a bottleneck in the overall process.

Surgical suites at hospitals must be equipped to handle the regular daily surgery schedule as well as urgent add-on cases. ASCs, on the other hand, are designed to perform nonurgent outpatient surgeries with minimal resources and therefore at a lower cost. Many characteristics of the OR environment are the same whether the surgery is performed in a hospital or in an ASC. A typical surgical suite is composed of several individual ORs sharing resources such as an equipment storage area, sterilization resources, preoperative

Figure 1. Stages of a perioperative system.

intake, and postoperative recovery rooms. Depending on the type of surgery, some ORs might have different technological resources. For instance, some types of cardiac surgery require cardiopulmonary bypass equipment. In some cases, these special resources may be dedicated to the ORs, while in others they may be mobile and transferred between ORs as needed.

The design and layout of a surgical suite can influence surgery scheduling. Traditional surgical suites have separate intake, surgery, and recovery areas. The patients enter the intake area, progress to surgery, and then eventually transition to a separate recovery area. Figure 2 illustrates the patient flow through this type of a surgical suite. More modern designs have experimented with a common intake and recovery area. The patient is allocated to a room, referred to as a *pre/post room*, where the intake process is carried out. The patient is subsequently taken to surgery, and then returned to their pre/post room after surgery [1].

The process for scheduling surgeries may differ from one hospital or ASC to another. One common system used by many hospitals is known as *block-booking*. In a block-booking system, blocks of uninterrupted OR time are reserved for individual surgeons or surgical specialties in a periodic (often weekly or monthly) schedule. Surgeons book cases into their allotted block time only if the surgery can be completed within the assigned time (or if an administrative exception is granted). The amount of block time is based on the surgeon's or surgical specialty's historical OR usage or some other performance criteria.

Other constraints such as surgeon preferences and resource availability are also taken into account when assigning block times.

Another scheduling approach used by some hospitals is *nonblocked* or *open-booking*. In these systems, surgeons submit requests for OR time. Surgeries are scheduled on a first-come-first-serve basis until either a maximum number of cases is reached or a predetermined OR capacity (planned available time) is reached [2]. Surgeons can submit their cases up until the day before surgery at which point a schedule is generated for the surgical listing.

In both block-booking and open-booking systems, a detailed schedule of surgeries is generated which includes surgery-to-OR assignments and estimated start times. On the day of surgery, the schedule (whether based on block-booking or open-booking) is revised by the OR manager (often an anesthesiologist or the head nurse) throughout the day to accommodate additional add-on cases, and to compensate for cases that run longer or shorter than expected. Both of these systems have advantages and disadvantages. In open-booking systems, surgeries are scheduled on short notice and uncertain demand gives rise to variable OR utilization rates [2]. Block-booking often overcomes this disadvantage by allocating blocks of OR time to surgical specialties based on historical utilization rates. However, it does not allow blocked OR time to be used for other specialties or surgeons, which can result in unused OR time.

Many hospitals use systems that are combinations of open-booking and block-booking systems. For instance, surgeons or surgical

Figure 2. Patient flow through a surgical suite.

specialties may share their assigned block time if it is unutilized within a certain lead time prior to the day of surgery. Furthermore, within the same surgical suite, some ORs may strictly follow a block-booking system, whereas others may follow an open-booking system.

Managing a surgical suite is complicated because it involves many levels of decision making that affect or are affected by surgery scheduling systems [3]. Strategic decisions take place over long time periods (e.g., one year) and include decisions such as whether to use an open-booking or block-booking system, major capacity decisions such as the number of ORs to utilize, investment in new technology, and the number and type of staff to employ. Tactical level decision making involves reserving OR time and capacity for surgical specialties, finding an efficient surgery mix, and determining how much time to plan for each type of surgery. These decisions involve balancing the cost of allocating too much time which causes idle time both for the OR and the staff with the cost of allocating too little time which may result in overtime. Operational decisions involve sequencing surgeries in a particular OR, estimating start times for individual surgeries [4], and setting appointment times for patients to arrive for surgery so as to minimize on-site waiting and achieve high patient satisfaction. In addition, decisions about how to manage add-on cases, and whether to cancel scheduled cases must be made on the day of surgery [3].

COMPLICATING FACTORS IN SURGERY SCHEDULING

Each activity in the perioperative period is critical to the successful delivery of surgical services to patients. The types of activities and their durations may differ from inpatient to outpatient settings and from one hospital to another. One commonality is that most of these activities have significant uncertainty in duration. This is well known for surgical procedures themselves and has also been reported for preoperative and postoperative time in ASCs [1]. Preoperative time, for instance, can depend on

many factors including whether the patient requires some prescreening (e.g., a patient with diabetes might require a blood test prior to surgery) or if the patient requires a translator. The surgery itself can be highly uncertain in duration. Factors affecting surgery include the type of procedure, physical characteristics of the patient such as body-mass-index, age, gender, and the surgical environment (e.g., academic vs nonacademic medical center or hospital vs outpatient procedure center) [5]. Uncertainty in postoperative time can result from the outcome of surgery and the patient's response to anesthesia. Previous research indicates that surgery duration and anesthesia duration often fit a lognormal distribution [4]. Although perfect prediction of surgery durations is impossible, improved estimates can have a positive impact on costs associated with underutilization and overutilization of the surgery suite.

Another complicating factor in surgery scheduling is the uncertainty in the number of patients to be scheduled on a particular day. Surgery at hospitals can be divided into two major categories such as *elective* and *non-elective* cases [6]. For elective cases, surgery may be planned well in advance (e.g., months) to be performed on a future date. For nonelective cases, on the other hand, the surgery is unanticipated. These cases must be worked into the existing schedule, either by using intentionally reserved or otherwise available space in the schedule, or by creating space by canceling elective cases. Some hospitals allocate separate ORs for emergencies and add-ons, whereas others allow slack time in the schedule [7,8].

Other causes of uncertainty in the number of surgeries on a particular day include patient punctuality, no-shows, or cancellations [9]. Outpatient settings are more affected by patient punctuality and no-shows. In inpatient settings, due to the greater complexity and risk of surgery, cancellations are a significant source of uncertainty. For instance, a cancellation may occur due to unexpected changes in the patient's medical status.

Variation and uncertainty in daily surgery mix is another complicating factor due to the varying resource requirements for different

types of surgery. Hospitals often control the mix by allocating OR capacity to specific surgical groups (e.g., thoracic, orthopedic, and colorectal). Such allocation, often called *block-booking*, is done based on historical utilization by surgical groups.

Surgical suites have high fixed costs, the large proportion of which are associated with the labor cost of the OR team. Surgical suites also have variable costs related to scheduling. For instance, ORs typically have a planned utilization time (e.g., 8 h) beyond which overtime costs for some members of the OR team begin to accrue. Therefore, on-time surgery start performance, to the extent it affects overtime, is an important consideration. Efficient surgery scheduling also affects the amount of waiting by the OR team, and other critical resources. The recovery area can also be the bottleneck for the surgical suite at certain times of the day. Therefore, resources such as PACU, ICU, and other hospital beds required after surgery and staff should be considered during the scheduling process [10].

High fixed costs encourage scheduling a sufficient number of cases to fully utilize capacity on the day of surgery. This pressure combined with complex interdependency between activities, and the need to schedule a large number of activities with uncertain duration within a fixed time during the day makes for a very challenging scheduling problem. Not surprisingly, much of the literature has focused on stochastic models (e.g., discrete-event simulation, queueing, stochastic programming, and Markov decision processes). In the next section, we provide a detailed review of the relevant literature on surgery scheduling.

LITERATURE REVIEW ON SURGERY SCHEDULING

Surgery scheduling has been a widely studied topic in the medical and operations research fields. There are a number of previous literature reviews related to surgery scheduling. An early review [11] focuses on classifying the previous research based on various stages of decision making, performance measures such as OR utilization and costs, and

the scheduling process. A more recent review article provides detailed classifications based on surgery durations (deterministic or stochastic), patient arrivals (elective and nonelective), and operations research methodology [6]. Previous reviews of literature on general health care appointment scheduling (e.g., primary care clinics [12]) are also relevant to surgery scheduling. In our review, we emphasize recent studies that consider new and important aspects of surgery scheduling systems. We categorize the literature based on the type of OR methodology used, and use our literature review to identify opportunities for future research which we summarize in the section titled “Open Challenges and Future Research Areas.”

Queueing Models

There have been numerous queueing-based studies presented over the past several decades on the problem of scheduling patients for surgeries and outpatient clinic appointments [13–15]. Queueing research has focused on single server problems for which appointment decisions are economically significant. Although not directly applicable, scheduling problems from other contexts (e.g., manufacturing lines and other service systems) are also relevant to surgery scheduling. Much of this research is relevant to single-OR scheduling with open-booking systems. The aim of the single-OR scheduling problem is to assign start times for a certain number of surgeries to be scheduled in a particular OR on a given day. The scheduler must consider the variability in surgery durations. Clearly, the amount of waiting and idling between surgeries will be impacted by the choice of start times. Also, depending on the planned OR time, some overtime may occur at the end of the day. Figure 3 demonstrates the situations when these conditions occur in an OR. The section titled “Example” provides a specific example in this context.

In the above referenced queueing literature, the authors assume an infinite horizon and stationary service and arrival processes which are not typical in surgery scheduling environments. Some researchers propose more realistic queueing models with a finite horizon. For instance, Brahimi and

Figure 3. Single OR scheduling problem. The scheduler selects surgery start times. The solid line depicts one possible scenario which includes some waiting, idling, and overtime.

Worthington [16] develop a queueing system with a time-dependent Markovian arrival rate and discrete service time distributions ($M(t)/G/s$ queue) where the number of customers at any time is assumed to be finite. Wang [17] studies the scheduling problem both as a static scheduling problem in which a finite number of customers are scheduled at once, and as a dynamic scheduling problem in which an additional number of customers are scheduled one at a time after an initial batch of customers have been scheduled. He uses phase-type distributions to investigate the transient solution of a Markovian server with general arrival distribution ($S(n)/M/1$ queue) to determine optimal start times for each customer.

Vanden Bosch and Dietz [18] present a queueing model with phase-type service durations and deterministic arrivals where patient no-shows are also considered. In their study, patients are classified into different groups depending on their service durations. Analyzing the special structure of the model, they propose an algorithm which is guaranteed to find the optimal schedule along with the optimal sequence efficiently.

Although not directly applicable to surgery scheduling, it is worth mentioning the recent study by Zeng *et al.* [19] on overbooking in clinical appointment schedules to reduce the negative impact of no-shows. The authors develop a queueing model with patients having different no-show probabilities. They propose that overbooking is beneficial for open-booking systems, and

they demonstrate that clustering patients according to their no-show probabilities will produce better schedules.

Queueing models offer valuable general insights about the effect of uncertainty on scheduling decisions. They also have several shortcomings in the context of surgery scheduling. Some of the queueing articles referred above assume that the system reaches steady state. However, surgical suites typically operate for some specific period of time during the day (e.g., 8–12 h) after which a small number of ORs are available for emergencies. Thus, the system is terminating, and the steady-state assumption is a significant approximation that has not been carefully validated. Queueing models also often require strong assumptions such as exponentially distributed surgery durations, which is not reasonable for most types of surgery that tend to better fit a lognormal distribution [4].

Simulation

Simulation models have found considerable application to surgery planning and scheduling. Although they do not provide closed form solutions like the queueing models, simulation models are more flexible in terms of assumptions about the probability distributions of surgery or other activity durations. However, they are also more computationally intensive than queueing models.

Ho and Lau [20] used simulation in their studies to compare the performance of

simple scheduling rules in a single server system. They propose that the performance of the scheduling rules are affected by the *environmental conditions* of the operating environment such as the probability of no-shows, number of patients to schedule, and the service distribution. They consider simple rules such as scheduling two, three, or more patients simultaneously at the beginning of the session and scheduling the later patients with intervals equal to the mean of the service distribution. They also modified these rules by changing the interval length between patients. In total, they evaluated more than 50 different rules with several different combinations of the three environmental conditions. They present the Pareto set of scheduling rules with respect to expected idle time of the server and expected patient waiting time.

Many researchers have used simulation methods to analyze more complex multi-OR surgical environments with recovery areas. Schmitz and Kwak [21], for example, used simulation to analyze a multi-OR surgical suite with recovery rooms to determine the number of ORs to open on a day given that the number of surgeries to be performed is known. They also study the impact of an increase in the number of ORs on recovery room usage and determine the need for recovery room capacity given that some of the surgeries are done in the outpatient setting. Lowery [22] simulates patient flow through a hospital's critical care units including ORs, ICU, and PACU beds to determine the bed requirements for these recovery units.

Simulation methods have been widely used for testing the performance of scheduling heuristics. In [1], a discrete event simulation model is developed for a newly designed outpatient surgical suite to study the impact of scheduling and start time heuristics and the daily surgical mix on the expected patient waiting time and overtime. The authors tested the performance of seven combinations of OR allocation heuristics and sequencing rules such as scheduling surgeries according to longest processing time first (LPT), shortest processing time first (SPT), increasing variance (VAR), and increasing covariance (COV), and found

that in general LPT and combination of LPT and VAR rules (LPT-VAR) perform better than other rules. The authors also found that arrival time schedules and daily surgery mix have significant effects on the performance measures while scheduling rules have smaller effects on the performance measures. The authors also compare the performances of the heuristics with a bi-criteria genetic algorithm which finds near optimal solutions.

Examining a surgery planning from a strategic perspective, Everett [23] developed a decision support system based on a discrete event simulation model to analyze the waiting times of surgery patients in a public health-care system with multiple hospitals in Australia. His model includes a single list for all surgical patients categorized by urgency and surgery type and can be used to match availability of the hospitals' and patients' needs. This simulation model considers each hospital as an entity in a large health-care system which may reflect the publicly funded health systems, such as in Canada, United Kingdom, and Australia, where there is more centralized control over the assignment of patients to health providers. The article provides evidence that the health-care policies used in different countries may influence the process as well as the efficiency in surgery scheduling.

Simulation models have generally found wide usage in the area of surgery planning and scheduling. Their flexibility allows them to consider many important factors relevant to complex surgical suites. Furthermore, they are descriptive models, meaning that they can be used to compare alternative policies or rules for planning and scheduling. However, there are also some shortcomings. First, they are computationally intensive. Secondly, generating results can be time-consuming compared to queueing models for which analytic solutions are available. A third important shortcoming of simulation models is that they do not provide optimal solutions.

Optimization

Optimization techniques have been widely applied to surgery scheduling. Many researchers have used deterministic models

for scheduling surgeries. Some have also used stochastic optimization models in order to incorporate uncertainties related to surgery durations and patient arrivals. We begin by describing deterministic models and then move on to stochastic optimization models.

Ozkarahan [2] proposed a goal programming model for scheduling surgeries in a surgical suite where block-booking is used for scheduling. Her model includes multiple objectives such as OR utilization, OR and surgeon preferences, and intensive care capacity. For each of these objectives, a goal is specified and the objective is to minimize the deviations from these goals.

Pham and Klinkert [24] extended the job shop scheduling problem to a *multimode blocking job shop* in order to satisfy resource constraints (modes) specific to the OR environment. They use a mixed integer programming (MIP) model formulation with the objective of minimizing the weighted sum of makespan and the sum of starting times of all procedures. They propose that add-on and emergency surgeries can be scheduled by adding new constraints using *job insertion*. Job insertion inserts new surgeries into the established schedule and bumps some elective surgeries to the following day, if necessary, to perform emergent surgeries. Fei *et al.* [25] have developed an integer programming (IP) model to assign elective surgeries with deterministic durations into multiple ORs. The objective is to minimize the weighted sum of overutilization and underutilization of ORs. They solve instances optimally with a branch and price algorithm.

There are also a number of stochastic optimization models for surgery scheduling. The majority assume a single OR, and determine optimal start times for surgeries (see Fig 3). Weiss [26] provides the optimal start times for a simple two-surgery problem with uncertain surgery durations in a single OR. Balancing surgeon's idle time and waiting time, the author shows that the problem is equivalent to the well-known *news vendor* problem from inventory theory, for which the optimal solution is known in closed form. Weiss also examines the optimal sequence of two cases by examining the expected cost resulting from the sequences and shows that

the sequencing decision is related to the dispersion of the density function of surgery durations. He proposes that scheduling surgeries that have distributions with "fatter" tails first results in higher total expected costs of waiting and idling due to the impact on the following surgery.

Denton and Gupta [27] study a general two-stage stochastic linear programming formulation of the single server appointment scheduling problem. They determine the optimal start times for surgeries. The criteria in their model are expected patient waiting time, expected OR idle time, and expected overtime with respect to a defined length of day. They develop an iterative approximate method based on upper and lower bounds on the optimal solution to the problem with continuously distributed surgery durations. More recently, Begen and Queyranne [28] studied the same problem with random service durations given by a joint discrete probability distribution. They prove that there exists an optimal appointment schedule which is integer and can be found in polynomial time.

Gerchak *et al.* [7] use a stochastic dynamic programming model for a multiperiod surgery scheduling problem. In particular, they use a Markov decision process to investigate the optimality of using *cut-off policies* in an open-booking system. Cut-off policies suggest rejecting future elective cases in order to be able to accept possible emergent surgeries if a certain number of ORs are already occupied by elective cases. The authors show that these cut-off policies are not necessarily optimal; however, they are typically close to optimal. Lamiri *et al.* [29] propose a stochastic model for scheduling elective surgeries over a planning horizon, however, they consider OR capacity for both elective and add-on patients. They use simulation to generate samples for emergency surgeries. The samples are used to estimate deterministic capacity requirements for an MIP model that minimizes total overtime costs and other costs associated with hospitalization, and penalties for waiting time of the patients, violating patient's and surgeon's preferences and deadlines. Their model is solved via branch-and-bound algorithm and

then compared to the solution of a simulation optimization approach. The authors conclude that simulation optimization offers improvements even for small sample sizes.

Denton *et al.* [30] proposed a two-stage stochastic MIP formulation to find optimal allocation of surgery blocks to ORs. They also develop a *robust formulation* which aims to minimize the maximum cost (worst-case outcome) that may result from the set of uncertain surgery durations. The robust formulation is advantageous when limited data is available for surgery durations. It is also much less computationally intensive than their stochastic programming model. Batun *et al.* [31] model a multi-OR scheduling problem as a stochastic MIP to determine the number of ORs to open on a given day, allocation of surgeries to ORs, sequence of surgeries within each OR, and start times for each surgeon. The focus of their study is on parallel scheduling of surgeries in which a surgeon may be allocated two or more ORs on the day of surgery.

Lamiri *et al.* [32] used a column generation approach to find the assignments of the elective surgeries into ORs on a given day in the planning horizon. The authors formulate the problem as a stochastic IP model and reserve a random capacity for emergency surgeries. Column generation is used as a solution technique in which columns represent possible surgery-to-OR assignments in a given planning horizon.

Despite the wide literature on optimization methods in OR scheduling problems, there is still a lack of literature in optimization of multi-OR surgical suite scheduling. The current literature suggests that considering the stochastic aspects of the surgical environment is essential for solving realistic problems. However, optimization methods have disadvantages as the problem size gets larger. Finding the optimal solution becomes computationally harder and sometimes impossible for large-scale realistic scheduling problems. Developing efficient stochastic optimization methods to solve larger and more realistic problems, which consider multiple ORs and other critical resources in the surgical suite, remains as an open challenge for researchers.

Heuristic Methods

As described in the previous section, the stochastic and combinatorial nature of surgery scheduling problems gives rise to computationally challenging optimization models. Many researchers have addressed this problem by proposing fast heuristics. This enables consideration of more complex and more realistic systems such as a multi-OR surgical suite with recovery rooms.

Denton *et al.* [33] consider a two-stage stochastic MIP model of the single OR scheduling problem with the addition of surgery sequencing. Decisions in their model are the optimal start times for surgeries and the optimal sequence of surgeries. A simple interchange heuristic is used to find near-optimal sequences, and start time decisions are computed to optimality for each sequence generated by the interchange heuristic. They also prove for a two-surgery example, conditions under which a stochastic ordering defines the optimal sequence, and use numerical experiments to demonstrate that sequencing in order of increasing variance of surgery duration is typically optimal or near-optimal. Intuitively, this is because delaying highly uncertain surgeries to the end of the day limits their impact on other surgeries in the schedule. Vanden Bosch and Dietz [34] propose a local heuristic method to sequence the customers in a first-come-first-serve appointment system when customers differ by waiting cost, no-show probability, and service time distributions. They also propose a solution method to find the optimal schedule given a fixed sequence.

Beliën and Demeulemeester [35] propose a simulated annealing approach as well as several different MIP heuristics to create a master surgery schedule for a block-booking system with the objective of minimizing the expected shortage of beds. Their MIP heuristics involve solving a number of MIPs, which aim to minimize the maximum expected duration, maximum expected bed occupancy, and maximum weighted sum of mean and variance of the daily bed occupancy respectively. Their simulated annealing approach, on the other hand, starts with a random surgery block and does pairwise exchanges

of blocks to find an improved schedule with respect to bed shortage.

Bin-packing algorithms have been widely used to find the mix of surgical cases for multi-OR surgical environments [36]. In this context, the ORs are available for a fixed time during the day, and represent the bins. The surgeries, which have an estimated duration, are the items to be packed in the bins. There are two types of bin-packing problems that have been studied: *on-line* and *off-line*. In the on-line bin-packing problem, urgent surgeries are scheduled sequentially one at a time. Many heuristics have been proposed for this problem. One well-known heuristic, called *best fit*, schedules surgeries into the OR which has the least amount of remaining time that is sufficient to fit the case. Another heuristic, called *worst fit*, schedules the surgery into the emptiest OR which has enough time to fit the case.

In the off-line version of the bin-packing problem, surgeries are batched and simultaneously assigned to ORs. LPT is the best-known heuristic for off-line bin packing. To apply LPT, surgeries are sorted based on their mean durations and then assigned sequentially to the ORs. Many variants of LPT exist including *best fit descending* in which surgeries are assigned sequentially to the fullest OR after being sorted by LPT rule and *worst fit descending* in which they are assigned to the emptiest OR. Dexter *et al.* [36] compare several of these heuristics for scheduling add-on surgeries into remaining open OR times. They found that off-line algorithms are able to fit more add-on surgeries and in particular *best fit descending with special constraints* is more likely to maximize OR utilization.

Hans *et al.* [37] study the bin-packing heuristics with the *portfolio effect* to consider the uncertainty in surgery durations. Portfolio management is used to reduce the risk (minimize variance) or increase the profitability (maximize expected return) by distributing the investments into various different projects instead of investing in a single project. They propose both constructive and local search heuristics to minimize the total planned slack time between surgeries depending on the variances of different

surgery durations. They found that, as a result of the portfolio effect, surgeries with similar duration variability are often scheduled on the same day for each specialty.

In general, heuristics provide a powerful trade-off between descriptive models, such as simulation and queueing models, and prescriptive (optimization) models for problems that are very computationally challenging. The main shortcoming of heuristics is that they do not necessarily provide an optimal solution and it is often difficult to develop good bounds on their performance.

EXAMPLE

In this section, we provide a small stochastic programming example on surgery scheduling. In this example, we consider a problem similar to the one illustrated in Fig. 3 with five surgeries to be scheduled on a given day. Surgery durations are distributed uniformly between 60 and 120 min. The length of the day is assumed to be 450 min. The optimal start times for the surgeries can be found by solving the following minimization problem:

$$\min_x \left\{ E \left[c^w \sum_{i=1}^5 w_i + c^\ell \ell \right] \right\} \quad (1)$$

where $x_i, i = 1, \dots, 4$, are the time allowances between start times of each of the surgeries, $w_i, i = 1, \dots, 5$, are the waiting times, and ℓ is the overtime. Overtime cost and waiting cost are assumed to be equal, that is, $c^w = c^\ell = 1$ in this example. The model in Equation (1) can be formulated as a two-stage stochastic linear program. The x_i are the first stage decision variables, and w_i and ℓ are second stage decisions which are made after the first stage decisions [27]. It is assumed that the first surgery is scheduled at time zero. Thus the waiting time for this surgery is zero.

The optimal solution to this two-stage stochastic programming problem is $x_1 = 95.11, x_2 = 99.73, x_3 = 99.40, x_4 = 96.01$ which means that after first surgery is scheduled at time zero, second one will be scheduled at time 95.11, third one at time 194.84, fourth one at time 294.24, and the

last one at time 390.25. The total expected waiting time plus overtime cost of this solution is 65.39.

A common practice is to set x_i equal to the mean of the duration distribution estimated based on historical data. Stochastic programming takes this uncertainty into account by sampling surgery duration scenarios to find a near-optimal solution which works well on average across all the possible scenarios. For this particular example, 10,000 different duration scenarios were used to find the optimal solution. If the mean value solution was used for this example, the total expected waiting time plus overtime cost would be 79.93, which is 22% higher than the total cost of the stochastic programming solution. Note that the optimal solution trades off expected waiting time cost and idle time cost, which are competing performance measures. For instance, short allowances tend to result in longer waiting time but shorter idle time. Alternatively, long allowances tend to result in shorter waiting times and longer idle times.

OPEN CHALLENGES AND FUTURE RESEARCH AREAS

In this article, we have so far provided an overview of important aspects related to surgery scheduling and a discussion of some of the most significant complicating factors. Surgery scheduling has been a topic of investigation for several decades. However, there are many open research areas and opportunities still to be explored. We describe some of these below.

Most of the above referenced literature focuses on the design of daily schedules prior to the day of surgery. Little effort has been spent on developing rules for real time scheduling on the day of surgery. This is a common problem that OR managers have to face every day to manage the deviations caused by the surgeries that run longer or shorter than anticipated. In addition to the daily operational level scheduling problem, there are also aspects of long range surgery planning and scheduling that need more attention. For instance, the vast majority

of the current literature focuses on patient waiting time on the day of surgery, when, in fact, the time spent in waiting lists may be more important from the health outcomes perspective.

Despite the rich literature considering the uncertainty in surgery durations, demand uncertainty is still largely unexplored. For instance, uncertainty in patient no-shows, case cancellations, and the addition of add-on cases to schedules on short notice can all have significant impact on surgery schedules. Most research has assumed that a fixed number of elective cases are to be scheduled. Uncertainty in demand from day to day can have a significant impact on surgery schedules resulting in substantial delays or cancellations on the day of surgery. Other causes of uncertainty such as unpredictable internal demand on recovery room resources on the day of surgery (e.g., ICU beds) are also in need of study.

Many of the studies referenced above focus on ORs; however, other parts of the surgical suite can also influence performance. For instance, the PACU can become a bottleneck, leading to patients backing up in ORs, and causing longer than anticipated turnover times between surgeries. This could ultimately result in overtime or surgery cancellations. Uncertainty in other critical activities like recovery time have been considered in the literature and demonstrated to be important considerations in scheduling. Some of the above referenced literature on simulation and deterministic mathematical programming consider this issue [10]; however, few attempts have been made to incorporate these aspects into stochastic optimization models.

Another research area that needs further attention is the design of surgical suites and processes within and around the OR. This has emerged as a way to increase OR utilization by reducing nonoperative time and increasing throughput. For example, Sandberg *et al.* [38] proposed a new OR suite design called *OR of the future (ORF)* for technologically intensive surgeries with an intake room and early recovery room attached to the OR. They are motivated by the goal of performing some of the

preoperative and postoperative processes in parallel to increase throughput and decrease overtime. With this new structure, the goal is to perform anesthesia induction in the induction room while the OR is prepared for surgery. Early recovery is provided by an additional perioperative nurse, while the anesthesia personnel can move to the intake of the next patient. Further study is needed to analyze the impact of new designs, which will likely lead to opportunities to improve the efficiency of surgery scheduling.

In this article, we have discussed the basic concepts related to surgery planning and scheduling as well as the surgical environment and the resources. We have also presented a broad range of operations research and management science methodologies used in surgery scheduling. Though this is a very well-studied subject, there are still significant opportunities to improve.

Acknowledgments

HISTORY

The preconditions for founding the Swiss Operations Research Society (SVOR/ASRO) were laid by Prof. Dr. h. c. Daenzer, Director of the Institute for Management at the Swiss Federal Institute of Technology (ETH) in Zurich; Prof. Dr. h. c. Käfer, Professor for Management at the University of Zurich; and Prof. Dr. h. c. Linder, Professor for Statistics at the University of Geneva and the Swiss Federal Institute of Technology (ETH) in Zurich. They prepared the ground by a first symposium on OR, held on June 20 and 21, 1958, in Zurich. It was devoted to a first overview of research in operations research (OR), both in universities and within companies. There were already teachers at the universities active in the field: Krelle in St. Gallen, Künzi in Zurich,

Billeter in Fribourg, Ferraud in Geneva, Scheurer and Erard in Neuchatel, and Angehrn in Basel. Several young people were busy to apply OR in industry. Some of them later became professors at universities (Soom in St. Gallen, Weinberg at the Swiss Federal Institute of Technology in Zurich, and Nievergelt in St. Gallen).

Several eminent exponents of OR visited Switzerland during this period and gave talks (A.W. Tucker, L. Arnoff, R.W. Shepperd, A. Adam, R. Roy, and R. Henn, among others, who later became professor in St. Gallen). Furthermore, several talks and workshops took place at different places. Interest in OR was growing, as testified by the increasing number of participants at these events.

The desire to create an organization to coordinate and represent the activities in OR in Switzerland developed and became urgent. The Swiss Society for Statistics and Economy (Schweizerische Gesellschaft für Statistik und Volkswirtschaft, SGSV, founded 1864) had already hosted three study groups (one each for theoretical economy, statistics, and management). Therefore, it seemed appropriate to install a further, new study group devoted to OR. This was judged to be an interesting complement to the existing groups, as OR could be applied in all the three domains. Prof. Künzi, Prof. Daenzer, and Alexis Stravs, a young engineer, contacted the SGSV and were well received. Therefore, a founding committee was constituted, composed of the following members:

Universities

- E. Billeter, Fribourg
- W. Daenzer, ETH Zurich
- R. Henn, St. Gallen
- K. Käfer, Zurich
- Linder, Geneva/ETH Zurich
- J. Niehans, Zurich
- W. Wegmüller, Bern

Industry and Administration

- H. Angst, Swissair, Zurich
- A. Guisolan, Dept. of Defense, Bern
- E. Nievergelt, SBB/CFF/FFS (Swiss Federal Railways), Bern
- E. Soom, Landis and Gyr, Zug
- A. Stravs, ETHZ, Institute for Management, Zurich
- J.J. Weidman, Nestlé, La Tour de Peilz
- F. Weinberg, MFO (Maschinenfabrik Oerlikon, now ABB), Zurich

The general assembly of the Swiss Society for Statistics and Economy, which took place on May 12 and 13, 1961, in La Chaux de Fonds, approved the new study group, which formed on the name “Schweizerische Vereinigung für Operation Research/Association Suisse pour la Recherche Opérationnelle” (Swiss Association for Operations Research). Its first president was Prof. H.P. Künzi, professor at the University of Zurich and later also at the Swiss Federal Institute of Technology in Zurich. The opening symposium of the new association took place on September 15 and 16 in Zurich at the ETH featuring 14 talks mainly from the members of the founding committee. The symposium was followed by the first general assembly of the association. It confirmed H.P. Künzi as the president and elected the founding committee as its first board, with E. Stiefel, ETH Zurich, and Schraffl, Céligny, as additional members. At the time of the first general assembly the association had 261 members, among them 41 collective members (companies). They are considered as the founding members.

The association included in its activities different successful introductory courses into new hot subjects (such as dynamic programming, branch and bound methods, and decision under uncertainty). Many leading OR specialists were invited for talks (among others G.B. Dantzig, P.L. Hammer, and P. Wolfe). To advance the exchange between universities and industry, many visits of companies were organized under the title “Operations Research at Company x”. Workshops in OR were organized, first in Lenk, and later and till now together

with the postdoc program “Troisième cycle en rechercheopérationnelle” of the Universities of the French speaking part of Switzerland.

The association also engaged in international activities, especially with the German association (DGU: Deutsche Gesellschaft für Unternehmensforschung) in the beginning. The first common conference took place in 1971 in Zurich followed by another one 1975 in Interlaken (this time with the DGOR: Deutsche Gesellschaft für Operations Research). Later, similar conferences were organized with the Austrian association (ÖGOR: Österreichische Gesellschaft für Operations Research), namely, 1980 in Vienna, 1984 in Zurich, and 1987 in Graz. By its first president, H.P. Künzi, the Swiss Association for Operations Research was also involved in the well-known “Henn-Schubert-Künzi” workshops in Oberwolfach, Germany.

The journal “Industrielle Organisation,” of the Institute for Management of the ETH in Zurich, published Swiss work in OR for a long time. Of course, very soon Swiss authors started publishing in international journals. H.P. Künzi was together with W. Krelle, the first editor of the Springer series “Monographien zur Unternehmensforschung” (Monographs for Operations Research) and encouraged thereby the German literature in the field. Later, together with M. Beckman, he was again the first editor of the “Springer Lecture Notes in Operations Research and Mathematical Systems”, a series that was devoted to the fast publication of new research results.

In the early 1960s, no chair of operational research as such existed in most universities of western Switzerland; some courses were offered sparsely on an optional basis.

At EPUL (to become EPFL in 1969), research was starting in OR as parts of doctoral theses. In the early 1970s, chairs were created in some institutions, in particular, in EPFL, which played an active role under the leadership of Prof. Charles Blanc who had a crucial influence on the recognition and the subsequent introduction of OR in the engineering curricula.

From that moment, SVOR/ASRO also developed in western Switzerland (French speaking part of Switzerland), attracting

new members from academia as well as industry. Several courses on classical or emerging OR methods were organized in western Switzerland and were followed by many participants from industry and university. Doctoral students also attended these courses, and finally, a permanent organization was set up under the flag of the “Troisième cycle romand”.

The creation of the 3e cycle romand de recherche opérationnelle contributed substantially to reinforce the links between the various institutions in which OR was used and developed. Undoubtedly, the SVOR/ASRO benefited considerably from these efforts.

As a national OR Society, the SVOR/ASRO had to be present also at the European level and similarly in the world. The SVOR/ASRO was present in Brussels when EURO was created in January 1975. Our representative was Alexis Stravs, who with a great dedication attended practically all administrative meetings and never failed to report the latest developments to the current SVOR/ASRO officers. For years, he was the living memory of the Society at the European level. However, he was more than that since he was also the representative of SVOR/ASRO for IFORS, the International Federation of Operations Research Societies, which was founded in 1958. For several years A. Stravs was also a member of the IFORS External Affairs Committee.

Thanks to the efforts of A. Stravs and his successors, the SVOR/ASRO has always maintained very close links with both the European Association EURO and the International Federation IFORS.

For SVOR/ASRO, the fifth EURO Congress organized at EPFL in 1982 with the American Society TIMS was an excellent opportunity to attract more than 600 representatives of the OR community in the world to Switzerland.

In 1997 the International Conference on Mathematical Programming took place at EPFL organized by T. Liebling and D. de Werra it attracted more than a thousand participants.

It may be worth mentioning that IFORS also had between 2010 and 2012 Dominique

de Werra as the president. D. de Werra was the first OR Professor at EPFL in 1971 and the president of SVOR/ASRO from 1984 to 1986.

He was the president of EURO from 1987 to 1988, and in 2004, he was the president of the Gold Medal jury of EURO. D. de Werra received the EURO Gold Medal in 1995, and he was the IFORS Distinguished Lecturer in 2006.

As a consequence of the concrete presence of SVOR/ASRO in the world of OR, it is worth mentioning that among the seven treasurers who cover the existence of EURO, four are members of the SVOR/ASRO (J. Pasquier, J. Bovet, M. Widmer and P. Solot). Such a confidence may undoubtedly be explained by the excellent reputation of Swiss bankers at that time. In 2007, the EURO also presented Hans-Jakob Lüthi, professor of operations research at ETH in Zurich and an SVOR/ASRO committee member, and his group the EURO Excellence in Practice Award for their work on flexibility in energy risk management.

In the past 51 years, from 1961 to 2012, the SVOR/ASRO has had 10 presidents and approximately 62 committee members. Each of them has strongly contributed to the promotion and development of the OR discipline in Switzerland and abroad. The list of SVOR/ASRO presidents is presented here.

1961–1970: Hans Kuenzi, University of Zurich (deceased)

1970–1976: Erich Soom, University of St. Gallen

1976–1980: Jürg Kohlas, University of Fribourg

1980–1984: Peter Kall, University of Zurich

1984–1986: Dominique de Werra, EPFL Lausanne

1986–1996: Heinz Schiltknecht, Sandoz, Bâle

1996–2001: Alain Hertz, EPFL Lausanne

2001–2005: Philippe Solot, Aicos, Basel

2005–2011: Daniel Costa, Nestlé, Vevey

2011–: Luca Maria Gambardella, IDSIA-USI-SUPSI, Lugano

CURRENT ORGANIZATION

The main objectives of SVOR/ASRO are to promote OR in Switzerland, to bridge the gap between the theory and practice of OR, and to represent the interests of the Swiss OR community in all relevant organizations.

The SVOR/ASRO includes members of different types: individual members, collective members, and students. The society is managed by an executive committee composed of the president and other three to five members, including the treasurer, the bulletin editor, the secretary and the person responsible for the program. The committee is renewed every three years by the general assembly.

The site of the general assembly is set each year following two principles. In some cases, the general assembly is organized during the visit of industrial sites, such as logistics operators, production companies, and traffic control organizations, where a potential impact of OR solutions is foreseen. In other years, the general assembly is held during conferences that the association is organizing and sponsoring in Switzerland. In particular, the 50th SVOR/ASRO anniversary assembly was organized in Zurich, during the International Conference on Operations Research (OR 2011). This international conference of the three German-speaking OR societies GOR, ÖGOR, and SVOR was organized by the ETH and UNI Zurich under the patronage of SVOR/ASRO. The committee chairs Karl Schmedders, (University of Zurich) and Hans-Jakob Lüthi (ETH Zurich) organized the event with more than 620 lectures within 197 sessions and three plenary speakers, Dimitris Bertsimas, Kenneth Judd, and William Pulleyblank. We are proud to report that these efforts were well received by the 850 participants from around the world.

Since 2003, the SVOR/ASRO has organized 10 Swiss Operations Research Days, in collaboration with IBM Research, Zurich. Over the years, the annual Swiss Operations Research Days have established themselves as a unique opportunity for researchers from the Swiss academic community and IBM Research to learn about each other's work and interests and to exchange current research developments in OR. The aim is to

not only exchange knowledge but also promote collaboration, initiate new projects, and have a good time with inspiring discussions.

An important and appreciated tradition of SVOR/ASRO is to print two or three times per year a paper bulletin which reaches all members. The bulletin opens a window over the main initiatives and events which involve OR in Switzerland and abroad.

One of the most important activities of the association is to promote OR among students and young researchers, encouraging them to practice this fascinating discipline. In 1997, the SVOR/ASRO established an annual prize for the best Master's thesis in OR and a three-year prize for the best doctoral thesis carried out in Switzerland in OR disciplines. The SVOR/ASRO also organizes a competition among high school students to encourage them to enroll in programs of study in mathematics and OR. Since 2004, the SVOR/ASRO has organized, in collaboration with SATW (Swiss Academy of Technical Sciences), seven competitions involving more than 200 students across Switzerland.

The SVOR/ASRO has recently received very important news. The Conference of the University of Western Switzerland (CUSO) has decided to approve and support the new "doctoral program CUSO in Operations Research." This program, which replaces the "Troisième Cycle Romand de Recherche Opérationnelle," started in 1970, has the primary objective of maintaining the same level as in previous cycles and start new initiatives, encouraging the participation of PhD students. Long-term goals are promoting OR in Switzerland and increasing its visibility at the international level by creating a solid network between research groups in Switzerland. From now on two major annual seminars are planned. In addition to the traditional winter seminar in Zinal, a new summer seminar will be organized.

The following is a list of leading academic groups in OR in Switzerland.

- Decision Support Systems, Department of Informatics, University of Fribourg.
- EPFL, École Polytechnique Fédérale de Lausanne, Lausanne

- IDSIA, Istituto Dalle Molle di Studi sull'Intelligenza Artificiale, USI-SUPSI, Lugano
- Haute école de gestion de Genève
- Institute for Operations Research, Chair of Logistics Management, and Centre for Energy Policy and Economics, ETH Zurich
- Institute for Operations Research and Mathematics of Economics, University of Zurich
- ior/cf-HSG, Institute for Operations Research and Computational Finance, University of St. Gallen
- Institut universitaire Kurt Bösch, Sion
- Quantitative Methods, Department of Business Administration, University of Bern

- University of Applied Sciences of Western Switzerland
- University of Geneva
- University of Neuchâtel
- Zurich University of Applied Sciences

SYMMETRY HANDLING IN MIXED-INTEGER PROGRAMMING

JIM OSTROWSKI
Department of Management Sciences,
University of Waterloo, Waterloo,
Ontario, Canada

INTRODUCTION

A standard method for solving integer linear programs (ILPs) is *branch and bound*. In branch and bound, the set of feasible solutions is partitioned, forming more easily solved subproblems. The presence of symmetry means that many of these subspaces are equivalent in a sense we describe later. Only one member of each collection of equivalent subspaces needs to be explored. Failure to recognize that many subspaces are equivalent results in a waste of computational effort that can render an instance unsolvable by branch and bound.

In this article, we show how the presence of a high degree of symmetry can render branch-and-bound methods useless. We also discuss how to find the symmetry group of an ILP formulation as well as how to use the symmetry group to reduce the size of the feasible region. Unfortunately, it is not clear how to best use a problem's symmetry group to reduce the feasible region. We discuss three different methods geared at exploiting symmetry in this manner. Orbitopal fixing uses the symmetry present in graph partitioning problems to fix variables throughout the branch-and-bound tree. Isomorphism pruning and orbital branching consider general ILPs, exploiting symmetry by fixing variables throughout the branch-and-bound tree and, in the case of isomorphism pruning, pruning nodes.

SYMMETRY IN INTEGER PROGRAMMING

An ILP is the problem of finding values of decision variables that maximize a linear

function, subject to a set of linear constraints with the additional restriction that values of all variables should be integral. An ILP can be written as

$$Z_{\text{ILP}} = \max_{x \in \mathbb{Z}_+^n} \{c^T x \mid Ax \leq b\}, \quad (\text{ILP})$$

where $\mathbb{Z}_+^n$ denotes the set of n -dimensional nonnegative integer vectors, $A \in \mathbb{Q}^{m \times n}$, $b \in \mathbb{Q}^m$, and $c \in \mathbb{Q}^n$, where $\mathbb{Q}$ denotes the set of rational numbers. The set $\{x \in \mathbb{Z}_+^n \mid Ax \leq b\}$ is called the *feasible region* of the ILP, which we denote as $\mathcal{F}$. A point is *feasible* if it is in the feasible region. The function that is maximized is known as the *objective function*.

Consider the following ILP from Ref. 1:

$$\begin{aligned} Z_{\text{ILP}} = \max_{x \in \{0,1\}^{n+1}} \{ & x_{n+1} | 2x_1 + 2x_2 + \cdots + 2x_n \\ & + x_{n+1} = 2k + 1 \} \\ \text{where } & k \in \mathbb{Z}_+, k \leq n. \end{aligned} \quad (1)$$

The example in Equation (1) can be easily solved without using a computer for any choice of n and k . The sum $2x_1 + 2x_2 + \cdots + 2x_n + x_{n+1}$ must always be odd, forcing $x_{n+1} = 1$, and hence the objective function, to take the value 1. Despite the problem's obvious solution, traditional branch-and-bound methods cannot solve even modest-sized instances. Table 1 gives computational results obtained from solving small problem instances of Equation (1) using the commercial solver CPLEX with its cut generation features turned off.

For any $k \in \mathbb{Z}$, $0 \leq k < n$, there will be a fractional solution feasible to the LP relaxation of Equation (1) with $x_{n+1} = 0$. Thus, nodes in the branch-and-bound tree will not be pruned until either k variables are fixed to 1 or $n - k$ variables are fixed to 0. As a result, the enumeration tree will contain at least $\min(2^k, 2^{n-k})$ nodes. Inspection of the enumeration tree, however, reveals that most of the work performed by traditional branch and bound is unnecessary. Many nodes in the

Table 1. Computational effort required to solve Equation (2)

n	k	Time (s)	Nodes
20	5	3.24	54,262
20	6	6.97	116,278
20	7	12.24	203,400
20	8	17.83	293,928
20	9	21.68	352,714
20	10	21.74	352,714
25	5	13.86	23,228
25	6	38.96	657,798
25	7	92.71	1,562,273
30	5	42.7	736,284
30	6	160.15	2,629,573

tree represent isomorphic subproblems that need to be solved only once.

To illustrate this phenomenon, consider the specific instance:

$$\min_{x \in \{0,1\}^5} \{x_5 \mid 2x_1 + 2x_2 + 2x_3 + 2x_4 + x_5 = 3\}. \quad (2)$$

The tree shown in Fig. 1 is generated using traditional branch-and-bound methods, by branching on the fractional variable with the smallest index. This branching method is, in general, a poor branching strategy. However, in this instance, the branching strategy is guaranteed to produce the smallest tree. Only nodes for which the LP relaxation is feasible are included in the figure. The LP relaxations of all nonleaf nodes in the tree have optimal values of 0, while the optimal solutions to each of the leaf nodes is also an

optimal solution to the ILP (and hence has an objective value of 1).

Consider node D , the subproblem formed by fixing x_1 to 0 and x_2 to 1. We can rewrite the subproblem as

$$\min_{x \in \{0,1\}^5} \{x_5 \mid 2x_3 + 2x_4 + x_5 = 1\}. \quad (3)$$

Now consider node E , the subproblem formed by fixing x_1 to 0 and x_2 to 1. This subproblem can also be written as

$$\min_{x \in \{0,1\}^5} \{x_5 \mid 2x_3 + 2x_4 + x_5 = 1\}. \quad (4)$$

The subproblem at node D is isomorphic to the subproblem at node E . It is easy to see why traditional methods have difficulty with this type of problem as both nodes D and E are solved. It is not necessary to consider *both* nodes D and E , but traditional methods provide no way of recognizing that two nodes are isomorphic. Further inspection shows that there are many other nodes that represent isomorphic subproblems (for instance, nodes G , H , and I represent the same subproblem, as well as nodes L , M , N , and O).

Not only are isomorphic subproblems solved multiple times, but also the subproblems themselves can be difficult to solve. Note that an optimal solution is feasible in each node as shown in Fig. 1. Intuitively, nodes whose feasible region contains an optimal solution are more difficult to prune than nodes that do not because nodes with optimal solutions need more of the integrality gap to be closed.

**Figure 1.** Branching tree for example.

A good branch-and-bound algorithm should avoid solving isomorphic subproblems. Ideally, sets of isomorphic subproblems should be recognized during the branching process and all but one member of each set should be pruned. For example, node E can be pruned because it is isomorphic to node D ; nodes I and O can be pruned because they are isomorphic to nodes G and L , respectively. Pruning to avoid this repetition will significantly reduce the number of nodes in the enumeration tree, hopefully making even very large symmetric problems solvable by integer programming methods.

MATHEMATICAL PRELIMINARIES

The many isomorphic subproblems in the example arise because of the symmetry in Equation (2). To formalize the definition of symmetry, we need to briefly introduce some basic concepts from group theory. A thorough review of group theory can be found in Refs 2–4.

Let I^n be the ground set $\{1, \dots, n\}$. Let S^n be the collection of permutations of the ground set, that is, the collection of all functions π such that $\pi : I^n \rightarrow I^n$ is a one-to-one and onto (bijective) mapping. A binary operation acting on permutations is the *composition* operation, that is, $\pi_i \circ \pi_j = \pi_i(\pi_j)$. For notational convenience, a group containing permutations will be referred to only by the set of elements $\mathcal{G}$. S^n is the *symmetric group* of I^n . Any subset of S^n that satisfies the properties of a group is called a *permutation group*. To provide emphasis and to distinguish S^n from a general permutation group, S^n will often be referred to as *the complete symmetric group*.

Given a vector $\lambda \in \mathbb{R}^n$ and a permutation group $\mathcal{G}$, $\pi \in \mathcal{G}$ acts on λ by permuting its coordinates: $\pi(\lambda) = (\lambda_{\pi_1}, \lambda_{\pi_2}, \dots, \lambda_{\pi_n})$. A permutation group can also act on a collection of vectors. For $X \subset \mathbb{R}^n$, $X^{\mathcal{G}}$ is given by $\{\pi(x) | x \in X \text{ and } \pi \in \mathcal{G}\}$.

Cyclic notation is used to describe permutations. For any $i \in \{1, \dots, n\}$ and permutation π , π 's action on i can be represented by the sequence $(i, \pi(i), \pi^2(i), \dots)$, where $\pi^2(i) = \pi(\pi(i))$. Because $\mathcal{G}$ is a finite group, the elements of this sequence repeat. Let p be the

first power of π such that $\pi^p(i) = i$. The cycle $(i, \pi(i), \pi^2(i), \dots, \pi^{p-1}(i))$ can be used to describe how the permutation acts on a subset of the elements. The permutation maps i to $\pi(i)$. It also sends the element $\pi(i)$ to $\pi^2(i)$. The set I^n can be partitioned using subsets formed by cycles of π . The collection of cycles formed by the partition of I^n defines the permutation. For example, suppose π is a permutation with $\pi(1) = 1$, $\pi(2) = 3$, $\pi(3) = 2$, $\pi(4) = 5$, $\pi(5) = 4$. The permutation π can be written as $(1)(2, 3)(4, 5)$. Since π does not permute element 1, the cycle (1) need not be included. The permutation π can be written more succinctly as $(2, 3)(4, 5)$. For any element not found in a cycle, it can be assumed that the element is not changed by the permutation.

Let $\mathcal{G}$ be an arbitrary permutation group acting on $\{1, 2, \dots, n\}$. The group $\mathcal{G}$ can be extended to act on sets of elements. For $S \subseteq \{1, 2, \dots, n\}$, the set $\pi(S) = \{\pi(i) | i \in S\}$. For a point $z \in \mathbb{R}^n$, the *orbit* of z under the action of the group $\mathcal{G}$ is the set of all elements of $\mathbb{R}^n$ to which z can be mapped by permutations in $\mathcal{G}$, that is,

$$\text{orb}(\mathcal{G}, z) \stackrel{\text{def}}{=} \{z' \in \mathbb{R}^n | \exists \pi \in \mathcal{G} \text{ such that } z' = \pi(z)\} = \{\pi(z) | \pi \in \mathcal{G}\} = z^{\mathcal{G}}. \quad (5)$$

The notion of orbits can be extended to variables by considering the unit vector. We can consider variables x_i and x_j to be symmetric if $j \in \text{orb}(\{i\}, \mathcal{G})$. By definition, if $j \in \text{orb}(\{k\}, \mathcal{G})$, then $k \in \text{orb}(\{j\}, \mathcal{G})$, that is, the elements j and k share the same orbit. Therefore, the union of the orbits

$$\mathcal{O}(\mathcal{G}) \stackrel{\text{def}}{=} \bigcup_{j=1}^n \text{orb}(\{e_j\}, \mathcal{G}) \quad (6)$$

forms a partition of $I^n = \{1, 2, \dots, n\}$, which is referred to as the *orbital partition* of $\mathcal{G}$, or simply the *orbits* of $\mathcal{G}$. Any two elements of I^n whose corresponding unit vectors share an orbit under the group $\mathcal{G}$ are *equivalent* or *symmetric* with respect to $\mathcal{G}$.

The *stabilizer* of a set $S \subseteq I^n$ in $\mathcal{G}$ is the set of permutations in $\mathcal{G}$ that send S to itself:

$$\text{stab}(S, \mathcal{G}) = \{\pi \in \mathcal{G} | \pi(S) = S\}. \quad (7)$$

The stabilizer of S is a subgroup of $\mathcal{G}$. The set of permutations that stabilize each set in the collection $\{S_1, S_2, \dots, S_k\}$ is written as

$$\text{stab}(S_1, S_2, \dots, S_k, \mathcal{G}) = \bigcap_{j=1}^k \text{stab}(\{S_j\}, \mathcal{G}). \quad (8)$$

For any collection of permutations, $\mathcal{A}$, $\langle \mathcal{A} \rangle$ is defined to be the smallest group containing all permutations in $\mathcal{A}$. The group $\langle \mathcal{A} \rangle$ is the group generated by $\mathcal{A}$, and similarly the set $\mathcal{A}$ is a *generating set*, or *generator*, of $\langle \mathcal{A} \rangle$. Thus, any group can be compactly represented by a generating set.

Example 1. Let $\mathcal{A} \subset S^4$ consist of the permutations $\pi^1 = (2, 3)$ and $\pi^2 = (1, 4)$. $\langle \mathcal{A} \rangle = \{(), (1, 4), (2, 3), (1, 4)(2, 3)\}$ is the smallest group containing $\mathcal{A}$. The permutations π_1 and π_2 are generators of $\langle \mathcal{A} \rangle$. Because $\pi_1(1) = 1$ and $\pi_1(4) = 4$, $\pi_1 \in \text{Stab}(\{1\}, \langle \mathcal{A} \rangle)$, $\pi_1 \in \text{Stab}(\{4\}, \langle \mathcal{A} \rangle)$, and $\pi_1 \in \text{Stab}(\{1\}, \{4\}, \langle \mathcal{A} \rangle)$. In addition, $\pi_1 \in \text{Stab}(\{2, 3\}, \langle \mathcal{A} \rangle)$ since elements 2 and 3 are not mapped outside the set $\{2, 3\}$. Since π_1 maps element 2–3, we have $\text{Orb}(\{2\}, \langle \mathcal{A} \rangle) = \{2, 3\}$. The orbital partition, $\mathcal{O}(\langle \mathcal{A} \rangle)$, is $(\{1, 4\}, \{2, 3\})$. We can also consider orbits of sets of elements. For example, $\text{orb}(\{1, 2\}, \langle \mathcal{A} \rangle) = (\{1, 2\}, \{1, 3\}, \{2, 4\}, \{3, 4\})$.

SYMMETRY GROUPS OF INTEGER LINEAR PROGRAMS

The *symmetry group* $\mathcal{G}(\text{ILP})$ of an integer program is the collection of permutations in S^n that map every feasible solution of (ILP) of value t to another feasible solution of (ILP) also of value t [5]. Formally,

$$\mathcal{G}(\text{ILP}) \stackrel{\text{def}}{=} \{\pi \in S^n \mid \forall x \in \mathcal{F}(\text{ILP}), \pi(x) \in \mathcal{F} \text{ and } c^T \pi(x) = c^T x\}. \quad (9)$$

Computing the symmetry group of a general ILP is NP-hard, and typically more difficult than solving the ILP itself. As a result, practical methods aimed at exploiting symmetries are forced to use a subset of the symmetry group that is found by examining the problem formulation.

Given a permutation $\pi \in S^n$ and a permutation $\sigma \in S^m$, let $A(\sigma, \pi)$ be the matrix obtained by permuting the columns of A by π and the rows of A by σ , that is, $A(\sigma, \pi) = P_\sigma A P_\pi$, where P_σ and P_π are appropriate permutation matrices. The *formulation group* $\mathcal{G}(A, b, c)$ of (ILP) is the set of permutations:

$$\mathcal{G}(A, b, c) \stackrel{\text{def}}{=} \{\pi \in \Pi^n \mid \pi(c) = c, \exists \sigma \in S^m \text{ with } \sigma(b) = b \text{ such that } A(\sigma, \pi) = A\}. \quad (10)$$

For any $\pi \in \mathcal{G}(A, b, c)$, if $\hat{x}$ is feasible for (ILP) (or the LP relaxations of (ILP)), then $\pi(\hat{x})$ is also feasible. Moreover, the solutions $\hat{x}$ and $\pi(\hat{x})$ have the same objective value. Thus, $\mathcal{G}(A, b, c) \subseteq \mathcal{G}(\text{ILP})$. As an example, we consider the following ILP:

Example 2.

$$\begin{aligned} \min \sum_{i=0}^8 x_i & \quad (11) \\ \text{subject to} & \\ x_0 + x_1 + x_2 + x_3 & \quad + x_6 \geq 1 \\ x_0 + x_1 + x_2 & \quad + x_4 \quad + x_7 \geq 1 \\ x_0 + x_1 + x_2 & \quad + x_5 \quad + x_8 \geq 1 \\ x_0 & \quad + x_3 + x_4 + x_5 + x_6 \geq 1 \\ x_1 & \quad + x_3 + x_4 + x_5 \quad + x_7 \geq 1 \\ x_2 + x_3 + x_4 + x_5 & \quad + x_8 \geq 1 \\ x_0 & \quad + x_3 \quad + x_6 + x_7 + x_8 \geq 1 \\ x_1 & \quad + x_4 \quad + x_6 + x_7 + x_8 \geq 1 \\ x_2 & \quad + x_5 + x_6 + x_7 + x_8 \geq 1 \\ x & \in \{0, 1\}^9 \end{aligned}$$

Consider the dominating set problem defined in Equation (11). The formulation group $\mathcal{G}(A, b, c)$ in this example contains 72 permutations. However, it can be generated using just four permutations. The generators are listed in Table 2 along with the corresponding σ such that $A(\sigma, \pi) = A$.

Because A is a symmetric matrix, each permutation π and its corresponding σ are identical. For general ILP problems, it is

Table 2. Generators for $\mathcal{G}(A, b, c)$

π	σ
(3, 6)(4, 7)(5, 8)	(3, 6)(4, 7)(5, 8)
(1, 2)(4, 5)(7, 8)	(1, 2)(4, 5)(7, 8)
(1, 3)(2, 6)(5, 7)	(1, 3)(2, 6)(5, 7)
(0, 1)(3, 4)(6, 7)	(0, 1)(3, 4)(6, 7)

Table 3. Generators for $\text{Stab}(\{0\}, \mathcal{G}(A, b, c))$

π
(3, 6)(4, 7)(5, 8)
(1, 2)(4, 5)(7, 8)
(1, 3)(2, 6)(5, 7)

unlikely that any such pair of permutations will be identical. Indeed, if A is not a square matrix, π and σ will not act on the same set of elements.

The orbital partition $\mathcal{O}(\mathcal{G}(A, b, c))$ consists of just one orbit, $\{0, 1, \dots, 8\}$. The stabilizer of 0 (i.e., $\text{stab}(\{0\}, \mathcal{G}(A, b, c))$) contains only eight permutations, listed in Table 3. The orbits of the stabilizer $\text{stab}(\{0\}, \mathcal{G}(A, b, c))$ are $\{0\}$, $\{1, 2, 3, 6\}$, and $\{4, 5, 7, 8\}$.

An optimal dominating set for the graph is the set $\{0, 3, 6\}$. We can find other equivalent solutions by permuting this set with any of the permutations in $\mathcal{G}(A, b, c)$. For example, consider permuting the set $\{0, 3, 6\}$ with the last generator, $(0, 1)(3, 4)(6, 7)$. In this case, $\{0, 3, 6\}$ is mapped to the set $\{1, 4, 7\}$. The cover consisting of $\{1, 4, 7\}$ is then an equivalent optimal solution.

The set of all optimal dominating sets equivalent to $\{0, 3, 6\}$, written as $\{0, 3, 6\}^{\mathcal{G}(A, b, c)}$, is the collection of sets:

$$\{0, 3, 6\}^{\mathcal{G}(A, b, c)} = \{\{0, 3, 6\}, \{1, 4, 7\}, \{2, 5, 8\}\}.$$

Not all optimal dominating sets are equivalent to the set $\{0, 3, 6\}$. For example, there is no permutation that maps the set $\{0, 3, 6\}$ to $\{0, 4, 8\}$. It is easy to see that $\{0, 3, 6\}$ and $\{0, 4, 8\}$ are not equivalent by noting that x_0 , x_3 , and x_6 appear together in a constraint (the first constraint), while the variables x_0 , x_4 , and x_8 do not. Another point of interest

can be seen by examining all sets equivalent to $\{0, 4, 8\}$:

$$\{0, 4, 8\}^{\mathcal{G}(A, b, c)} = \{\{0, 4, 6\}, \{0, 5, 7\}, \{1, 3, 8\}, \{1, 5, 6\}, \{2, 3, 7\}, \{2, 5, 6\}\}.$$

The number of solutions equivalent to a given solution is solution dependent, making it difficult to predict how many equivalent optimal solutions exist.

The equivalence of solutions induced by symmetry is a major factor that might confound the branch-and-bound process. For example, suppose that x^* is an (integral) optimal solution to a binary ILP. At the root node, the decision is made to branch on variable x_j , creating one subproblem by fixing $x_j = 0$ and another by fixing $x_j = 1$. If $\exists \pi \in \mathcal{G}(\text{ILP})$ such that $[\pi(x^*)]_j = 1 - x_j^*$, then x^* is a feasible solution for one child node and $\pi(x^*)$ is feasible for the other child node. In general, subproblems where feasible regions contain optimal solutions will be more difficult to solve because the proportion of the integrality gap that must be closed is greater than a subproblem that does not contain any optimal solution. If the cardinality of $\mathcal{G}(\text{ILP})$ is large, then there may be many such subproblems, leading to long solution times.

Note that the formulation group is very dependent on the problem formulation. For example, consider adding the constraint $\sum_{i=0}^8 2^i x_i \geq 0$ to Example 2. This constraint does not remove any feasible points from the LP relaxation and does not remove symmetry from the ILP, but it does remove all of the symmetry from the formulation.

COMPUTING SYMMETRY GROUPS AND FORMULATION GROUPS

Recall that the formulation group of an ILP is

$$\mathcal{G}(A, b, c) \stackrel{\text{def}}{=} \{\pi \in \Pi^n \mid \pi(c) = c, \exists \sigma \in S^m \text{ with } \sigma(b) = b \text{ such that } A(\sigma, \pi) = A\}. \quad (12)$$

A popular method of computing the formulation group is by constructing a graph whose automorphism group is similar to the formulation group [6–9].

In the case where A is a $(0, 1)$ -matrix and both c and b are vectors of ones, then the formulation group can be found by considering the bipartite graph, H , associated with the adjacency matrix:

$$\begin{pmatrix} A & 0 \\ 0 & A^t \end{pmatrix}. \quad (13)$$

The graph H contains vertices representing variables and vertices representing constraints. Permutations that map H to itself only make sense in the context of integer programming if they map variable-vertices to other variable-vertices (and likewise constraint-vertices to other constraint-vertices). Thus, if Γ is the symmetry group of H , then $\mathcal{G}(\text{ILP}) = \text{stab}(\{1, \dots, n\}, \Gamma)$. More general cases require the construction larger, colored graphs. Details can be found in Refs 10 and 11.

Computing the formulation group for an ILP is equivalent to the graph isomorphism problem. Graph isomorphism is neither known to be NP-hard nor to be polynomial time solvable [12], even when the graph is bipartite. However, current software such as nauty [13] and Saucy [14] are able to quickly compute the automorphism group of most reasonably sized graphs.

EXPLOITING SYMMETRY WHEN COMPUTING THE RELAXATION

Typically in integer programming, a relaxation of the ILP is formed by ignoring the integrality constraints on the variables, creating the linear program (LP). This gives a lower bound to the problem, which can then be used to prune nodes. The LP solver can use symmetry to reduce the size of the relaxation.

Let y be any feasible solution to the LP relaxation of (ILP) with symmetry group $\mathcal{G}$. By the definition of $\mathcal{G}$ and the convexity of $\mathcal{F}$, any linear combination of elements of $\{\pi(y) | \pi \in \mathcal{G}\}$ is in $\mathcal{F}$. As a result, an optimal solution, x^* , to the LP relaxation of the form $x^* = \frac{\sum_{\pi \in \mathcal{G}} \pi(x^*)}{|\mathcal{G}|}$ is guaranteed to exist.

Thus, the LP relaxation formed by adding the equalities $x_i = \frac{\sum_{\pi \in \mathcal{G}} \pi(x_i)}{|\mathcal{G}|}$ will provide an identical LP bound. For any $j \in \text{orb}(i, \mathcal{G})$, there is a permutation σ that sends j to i . Thus, $\frac{\sum_{\pi \in \mathcal{G}} \pi(x_j)}{|\mathcal{G}|} = \frac{\sum_{\pi \in \mathcal{G}} \pi(\sigma(x_i))}{|\mathcal{G}|}$. By the definition of a group, π and σ in $\mathcal{G}$ implies that $\pi(\sigma^{-1})$ is also in $\mathcal{G}$. Thus, $\frac{\sum_{\pi \in \mathcal{G}} \pi(\sigma(x_i))}{|\mathcal{G}|} = \frac{\sum_{\pi \in \mathcal{G}} \pi(x_i)}{|\mathcal{G}|}$.

Adding the constraints $x_i = \frac{\sum_{\pi \in \mathcal{G}} \pi(x_i)}{|\mathcal{G}|}$ for each i is equivalent to adding $x_i = x_j$ for all $j \in \text{orb}(i, \mathcal{G})$. Using these equalities, the number of variables can be reduced to the number of orbits in the partition $\mathcal{O}(\mathcal{G})$ (the number of constraints can be reduced in a similar way). This reduction can decrease the time required to solve the LP significantly; however, the given LP solution can be highly fractional.

Using the symmetry group to aid in the computation of the LP relaxation has not been a well-researched area. This is mostly due to the fact that most problems exhibiting a large degree of symmetry are very hard, and only instances of small size are solvable. For these problems, the LP relaxations are easy to solve. This is not the case, however, in the context of semidefinite programming (SDP). Some interesting work has been done at using symmetry to reduce the size of SDPs, particularly for the quadratic assignment problem [15].

REMOVING SYMMETRY FROM THE FEASIBLE REGION

Another class of symmetry-breaking algorithms uses the symmetry group of the problem to reduce the feasible region by removing sets of equivalent solutions. This strategy of reducing the feasible region allows for more general techniques than reformulation.

Recall Example 2, a dominating set problem on nine nodes. Let $\mathcal{G}$ be the symmetric group. At the root node, all variables in the problem share an orbit. Because it is clear that at least one variable must be equal to 1, an arbitrary variable can be chosen and fixed to 1. For example, x_0 can be fixed to 1. The reason for fixing x_0 to 1 is very intuitive. Any optimal solution must contain at least one variable with value 1. Suppose that in a given optimal solution, $\hat{x}$, there is a j with $\hat{x}_j = 1$ for some $j \in \{0, \dots, 8\}$.

Since all variables are symmetric at the root node, there is a permutation $\pi \in \mathcal{G}$ that maps element j to element 0. Then, $\pi(\hat{x})$ is feasible and optimal (by definition of $\mathcal{G}$) with $\pi(\hat{x}_0) = 1$. By setting $x_0 = 1$, solutions are removed from the feasible region, but every solution that is removed is symmetric to at least one solution remaining in the feasible region. Hence, fixing an arbitrary variable to 1 serves to remove some symmetry as well as to tighten the LP bound.

A similar technique is used in graph coloring problems. Given a graph G , a coloring is valid if no two adjacent vertices are assigned the same color. Given a valid coloring, equivalent valid colorings can be generated by relabeling colors. A typical integer program (IP) formulation for this problem contains binary variables x_i^j that represent if vertex i is colored j and binary variables y^l that represent if any vertex has color l . The mathematical formulation is

$$\begin{aligned} \min \quad & \sum_{l=1}^k y^l \\ \text{s.t.} \quad & x_i^l + x_j^l \leq y^l \quad \forall (i,j) \in E \quad \forall l \in \{1, \dots, k\} \\ & \sum_l x_i^l = 1 \quad \forall i \in V \\ & y^l, x_i^l \in \{0, 1\} \quad \forall i \in V \quad \forall l \in \{1, \dots, k\}. \end{aligned} \quad (14)$$

The symmetry group of formulation (14) contains the permutations

$$\begin{aligned} \pi_{l,m} &= (x_1^l, x_1^m)(x_2^l, x_2^m) \dots (x_n^l, x_n^m) \\ &\quad \forall l, m \in \{1, \dots, k\}, \quad l \neq m, \end{aligned}$$

simply meaning that colors can be arbitrarily relabeled.

Suppose that G contains a clique of size k . No two vertices in the clique can be assigned the same color. Given that no vertex is currently colored, each of the k vertices in the clique can be arbitrarily colored with each of the first k colors. As with fixing a variable to 1 in Example 2, this fixing of colors removes symmetric solutions from the feasible region and reduces the size of the symmetry group acting on the problem by at least a factor of $k!$.

As before, this fixing is valid because for each solution that is removed, there is at least one equivalent solution remaining in the feasible region. These intuitive fixing rules aim to reduce the size of the feasible region (as well as the symmetry) of the problem instance by removing a large set of feasible solutions. A solution can be removed as long as it is guaranteed that for each solution removed a *representative solution* (i.e., an equivalent solution) remains in the feasible region. This is formalized in Ref. 16 where Eric Friedman adapts a notion from geometry. For a permutation group Γ and a set $X \subset \mathbb{R}^n$, a *generalized fundamental domain* of X with respect to Γ is a subset F of X such that X can be constructed using the points in F along with the permutations in Γ , that is, $F^\Gamma = X$.

Formally, a set F is a generalized fundamental domain of X with respect to Γ if and only if for every $x \in X$, the set $\text{orb}(x, \Gamma) \cap F$ is nonempty. A fundamental domain is *minimal* if it does not contain a smaller fundamental domain.

Example 3. If $X = \{(0, 0), (1, 0), (0, 1), (1, 1)\}$ and $\Gamma = \{e, \pi = (1, 2)\}$, there are three different fundamental domains. The set X is a trivial a fundamental domain because $X^\Gamma = X$. In addition, the set $F_1 = \{(0, 0), (1, 0), (1, 1)\}$ is a fundamental domain. This can be seen by noting that the only element in X that is not in F_1 is the element $(0, 1)$, but $\pi((1, 0)) = (0, 1)$, so $F_1^\Gamma = X$. For the same reason, the set $F_2 = \{(0, 0), (0, 1), (1, 1)\}$ is also a fundamental domain. No two elements in F_1 are symmetric, so F_1 is a minimal fundamental domain with respect to Γ . Similarly, F_2 is also minimal.

For a polyhedron $X \subseteq \mathbb{R}^n$, a permutation group Γ , and an n -vector c consider the set

$$F_c(X, \Gamma) = \{x \in X \mid c^T x \geq c^T \pi(x) \quad \forall \pi \in \Gamma\}. \quad (15)$$

For any $x \in \mathcal{F}$, at least one element $y \in \text{orb}(x, \Gamma)$ satisfies the constraints $c^T y \geq c^T \pi(x) \forall \pi \in \Gamma$ so $F_c(X, \Gamma)$ is a fundamental domain of X with respect to Γ . If c is such that only one feasible solution

satisfies the set of constraints, then F_c is a minimal fundamental domain. One such c comes from enforcing a lexicographic ordering of the variables, that is, $c_{lex} = (2^{n-1}, 2^{n-2}, \dots, 2, 1)$. $F_{c_{lex}}$ is a minimal fundamental domain [16] for all $X \subseteq \{0, 1\}^n$ and Γ .

Example 4. For Example 2, the constraints of $F_{c_{lex}}$ that result from the generators of $\mathcal{G}$ are given in Table 4.

There is an immediate concern with using lexicographic constraints. Adding constraints that define $F_{c_{lex}}$ will cause problems for most numerical methods because of the magnitude of the coefficients in c_{lex} . However, these constraints guarantee that the resulting fundamental domain is minimal for any $X \subseteq \{0, 1\}^n$ and Γ . Despite the numerical issues, most literature focuses on choosing fundamental domains based on lexicographic ordering (generating fundamental domains by selecting lexicographic either maximal or minimal elements).

In the context of integer programming, X represents the set of feasible solutions, $\mathcal{F}$, to a problem and Γ represents the symmetry group of the problem, $\mathcal{G}$. By definition, for any fundamental domain F of $\mathcal{F}$ with respect to $\mathcal{G}$ (ILP), any optimal solution in $\mathcal{F}$ is symmetric to a solution in F . Hence,

$$\min_{x \in F} \{c^T x\} = \min_{x \in \mathcal{F}} \{c^T x\}. \quad (16)$$

Unfortunately, restricting the feasible region to $\mathcal{F}$ does not improve the LP bound values. This is because one representative of each set of symmetric integer solutions *and* fractional solutions remain in $\mathcal{F}$.

STATIC VERSUS DYNAMIC SYMMETRY-BREAKING METHODS

The search of (ILP) can be restricted to a fundamental domain. The issue then becomes how to choose a fundamental domain. Symmetry-breaking tools that use fundamental domains can be split into two different classes. Static symmetry-breaking methods determine the fundamental domain at the start of the algorithm, and dynamic methods determine the fundamental domain during the branching process.

Static symmetry-breaking methods can be very effective at solving highly symmetric problems. Methods such as adding symmetry-breaking constraints only require an alteration of the problem formulation and do not require special software. In addition, knowing the domain explicitly at every node in the tree makes it possible to fix variables based on the (implicit or explicit) fundamental domain constraints.

Static symmetry-breaking methods have some limitations. The first, as previously mentioned, is the potentially large number of inequalities needed to remove all of the symmetry from the problem. This problem can sometimes be avoided with clever algorithms. Secondly, restricting the search to an arbitrarily chosen fundamental domain could distort the branching process by changing the relative importance of the variables. For example, restricting the feasible region to the set of lexicographically minimal solutions would significantly increase the importance of variables with small indices. Algorithms that, in theory, have no branching restrictions may require branching in a rigid way to achieve the best results.

Static methods can make finding optimal solutions more difficult, as the solution found

Table 4. Lexicographic constraints

π	Lexicographical constraint
(3,6)(4,7)(5,8)	$32x_3 + 16x_4 + 8x_5 + 4x_6 + 2x_7 + x_8 \geq 32x_6 + 16x_7 + 8x_8 + 4x_3 + 2x_4 + x_5$
(1,2)(4,5)(7,8)	$128x_1 + 64x_2 + 16x_4 + 8x_5 + 2x_7 + x_8 \geq 128x_2 + 64x_1 + 16x_5 + 8x_4 + 2x_8 + x_7$
(1,3)(2,6)(5,7)	$128x_1 + 64x_2 + 31x_3 + 8x_5 + 4x_6 + 2x_7 \geq 128x_3 + 64x_6 + 32x_1 + 8x_7 + 4x_2 + 2x_5$
(0,1)(3,4)(6,7)	$256x_0 + 128x_1 + 32x_3 + 16x_4 + 4x_6 + 2x_7 \geq 256x_1 + 128x_0 + 32x_4 + 16x_3 + 4x_7 + 2x_6$

must also be in the chosen fundamental domain. Adding symmetry-breaking constraints to the root node may, in fact, remove optimal solutions that, along with a specified branching rule, would have been easier to find than the equivalent optimal solution remaining in the fundamental domain. This has been studied in the context of constraint programming in Ref. 17, where the authors show that branching strategies can drastically alter the time required to find solutions. The problem caused by pruning these easily found optimal solutions can be overcome with more intelligent branching. For instance, if the set of representative solutions is chosen based on a lexicographic order, then branching in that order would avoid this problem. However, rules like this are not ideal, as branching is very important in every integer program, not just those that contain symmetry. Therefore, choosing a branching rule *a priori* is not desirable.

Dynamic symmetry-breaking strategies differ from static methods because they construct the fundamental domain during the solution process, not *a priori*. Because the fundamental domain is not predefined, the branching decisions can influence the fundamental domain and not vice versa.

Because the fundamental domain is defined during the branching process, dynamic symmetry-breaking methods cannot use off-the-shelf software. To date, no such software exists. In addition, because the domain is not fully defined at nodes in the tree, fewer variables can be fixed than with static methods.

Symmetry-breaking strategies designed for specific problem classes are typically static methods. Meller *et al.* [18] attack symmetry in an optimal facility layout design using constraints that reduce the size of the fundamental domain. Sherali and Smith [19] present three different applications where symmetry arises: telecommunications network-design problems, noise pollution problems, and machine procurement and operation problems. They also discuss symmetry-reducing constraints for these specific problems. Mendez-Diaz and Zabala present formulations, as well as symmetry-breaking inequalities, for the graph coloring problem

[20]. They also present computational results investigating several different ways to handle symmetry [21].

Symmetry Breaking via Orbitopes

Explicitly stating all the lexicographic inequalities (as in Table 4) is not practical for many reasonably sized problems. One avenue of research is to find classes of problems for that there are efficient ways to enforce lexicographic ordering without adding exponentially many ill-conditioned constraints to the LP formulation. This is the purpose of [22]. In their work, Kaibel and Pfetsch consider the set of all 0/1 matrices of size $p \times q$, $\mathcal{M}_{p,q}$. Given a symmetry group $\mathcal{G}$ acting on the columns of such a matrix, they define the *full orbitope* $O_{p,q}(\mathcal{G})$ to be the convex hull set of matrices of $\mathcal{M}_{p,q}$ that are lexicographically maximal within their orbits (where the ordering of the variables is row by row). For example, the 0/1 matrix

$$X = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{pmatrix}$$

does not have lexicographically decreasing columns, so it is not in the orbitope $O_{5,4}(S^4)$. The permutation (3, 4) swaps columns 3 and 4, giving the matrix:

$$X' = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix}$$

The matrix X' has lexicographically decreasing columns, so it is in $O_{5,4}(S^4)$.

Kaibel and Pfetsch focus their attention on both *packing* and *partitioning orbitopes*, where either the cyclic group (C^q) or the complete symmetric group (S^q) acts on the columns. The packing orbitope, $O_{p,q}^{\leq}(\mathcal{G}) \subset O_{p,q}(\mathcal{G})$, consists of all lexicographically maximal 0/1 matrices where each row contains at most a single 1. The partitioning orbitope, $O_{p,q}^=(\mathcal{G}) \subset O_{p,q}(\mathcal{G})$, consists of all lexicographically maximal matrices where

each row contains exactly a single 1. Packing and partitioning orbitopes arise in a wide array of problems, like graph coloring and partitioning, bin packing, as well as some scheduling problems. It should be noted that the set-packing/partitioning need only occurs as a substructure of the problem at hand. Additional inequalities may be present, so long as their effect on the column symmetry group is accounted for.

Kaibel and Pfetsch [22] provide linear descriptions of all facet-defining inequalities for the convex hull of orbitopes $O_{p,q}^{\leq}(C^q)$, $O_{p,q}^{\leq}(S^q)$, $O_{p,q}^=(C^q)$, and $O_{p,q}^=(S^q)$. They also provide separation algorithms for all inequalities that run in polynomial time. The facet-defining inequalities have only $\{-1, 0, 1\}$ coefficients, avoiding the numerical issues that arise when lexicographic constraints are used to eliminate symmetry. However, to completely describe the polytope $O_{p,q}^{\leq}(S^q)$ and $O_{p,q}^=(S^q)$, an exponential number of linear inequalities is required.

This technique can be applied to classes of integer programming problems as follows. Elements in a partitioning orbitope represent possible solutions to IP formulations of set-partitioning problems such as graph coloring, while the packing orbitope represents solutions to IP formulations of set-packing problems. For example, imagine a set-partitioning problem in which items are placed in one of q indistinguishable sets. The variable $x_{i,j} = 1$ if item i is placed in set j . A solution to the problem can be represented as a $p \times q$ matrix, where p is the number of items and q is the number of sets. Since the sets are indistinguishable, any permutation of the sets will map feasible partitions to other feasible partitions. Therefore, every permutation of the columns is in the symmetry group. Symmetry in the formulation can be removed by adding the additional constraint that the solution must also be an element of the orbitope $O_{p,q}(S^q)$. Kaibel and Pfetsch [22] show that enforcing membership in either $O_{p,q}^{\leq}(C^q)$ or $O_{p,q}^=(C^q)$ is simple. Ensuring that the first column is the lexicographically largest column in the matrix is enough to guarantee that the matrix is in the appropriate orbitope. Note also that C^q contains only $q - 1$ permutations, so only $q - 1$

constraints are needed to enforce a lexicographic ordering.

Enforcing membership in either $O_{p,q}^{\leq}(S^q)$ or $O_{p,q}^=(S^q)$ is not as simple as it is for the cyclic group C^q . Kaibel and Pfetsch note that the projection of $O_{p,q}^=(S^q)$ is affinely isomorphic to $O_{p-1,q-1}^{\leq}(S^{q-1})$, so they restrict their attention to the orbitope $O_{p,q}^=(S^q)$. The main result of their work is that *shifted column inequalities* (SCIs), along with row-sum constraints and lower bound constraints, provide a complete linear description of $O_{p,q}^{\leq}(S^q)$. To describe the SCIs, some notation is necessary. A *bar* is formed by indices of the matrix

$$B = \{(i,j), (i,j+1), \dots, (i,q)\} \quad (17)$$

for some $2 \leq i \leq p$, $2 \leq j \leq \min\{i, q\}$. A *shifted column* (SC) is a set of indices

$$S = \{(i_1, j_1), (i_2, j_2), \dots, (i_\eta, j_\eta)\} \quad (18)$$

where $i_1 \leq i_2 \leq i_\eta$, $j_1 \leq j_2 \leq j_\eta \leq j$, and no two elements in S share the same diagonal in the matrix. For any bar B and SC S , they call $\sum_{(i,j) \in B} x_{i,j} \leq \sum_{(i,j) \in S} x_{i,j}$ a *shifted column inequality*. The orbitope $O_{p,q}^=(S^q)$ can be completely described by nonnegativity constraints, the row-sum equations $\sum_j x_{i,j} = 1$ for all i , and the SCIs formed by all bars and SCs.

Example 5. Figures 2–4 are three different SCs and bars. A “+” denotes elements in the bar while a “−” denotes elements in the SC.

Figure 2. Shifted column 1.

Figure 3. Shifted column 2.

Figure 4. Shifted column 3.

The inequalities derived from the SC and the bar inequalities are listed in Table 5.

Note that in partitioning problems $\sum_{(i,j) \in B} x_{i,j} \leq 1$. If an SCI is violated, it must be because $\sum_{(i,j) \in B} x_{i,j} = 1$ and $\sum_{(i,j) \in S} x_{i,j} = 0$. Consider an example of a matrix that violates the first SCI shown above. Clearly the matrix in Figure 5 is not lexicographically maximal, as column 4 can be swapped with column 5 to create a lexicographically larger matrix.

Kaibel *et al.* [23] use the linear time algorithm to fix variables throughout the enumeration tree. They call their fixing *orbitopal fixing*. They also test orbitopal fixing on a class of graph partitioning problems and compare it to a more general symmetry breaking method, isomorphism pruning, which is detailed in the following

Table 5. Shifted column and bar inequalities in orbitopes

Figure	Shifted column inequality
2	$x_{9,5} + x_{9,6} + x_{9,7} \leq x_{4,4} + x_{5,4} + x_{6,4} + x_{7,4} + x_{8,4}$
3	$x_{9,5} + x_{9,6} + x_{9,7} \leq x_{2,2} + x_{4,3} + x_{5,3} + x_{7,4} + x_{8,4}$
4	$x_{9,5} + x_{9,6} + x_{9,7} \leq x_{1,1} + x_{2,1} + x_{4,2} + x_{5,2} + x_{6,2}$

Figure 5. Matrix that does not satisfy SCI.

section. Unlike isomorphism pruning, using orbitopal fixing does not restrict branching behavior, and the results suggest that the gain in performance as a result of using orbitopal fixing over isomorphism pruning is a result of the flexible branching. Further efforts by Kaibel *et al.* [24] show that finding constraints for slightly more general orbitopes quickly becomes NP-hard. Finding orbitopal symmetries is discussed in Ref. 25.

Isomorphism Pruning

The leading approach for solving

$$\min_{x \in \{0,1\}^n} \{c^T x | Ax \leq b\}, \quad (19)$$

where Equation (19) is highly symmetric ($|\mathcal{G}(\text{BIP})|$ is large) and is isomorphism pruning, developed for integer programming by Margot [26–29]. Isomorphism pruning uses the branching decisions to generate a minimal fundamental domain dynamically. Let $\mathcal{T}$ be any branch-and-bound tree for

Equation (19) where nodes are only pruned if the LP relaxation is infeasible and not by bound. Each node at depth n in $\mathcal{T}$ has all variables fixed and, therefore, corresponds to a feasible integral solution of the ILP. The tree is oriented by letting the branch $x_i = 1$ be the left branch ($x_i = 0$ the right branch). The fundamental domain used by isomorphism pruning is defined by the branch-and-bound tree $\mathcal{T}$. The fundamental domain consists only of the leftmost element of each collection of equivalent feasible solutions. The goal of isomorphism pruning, then, is to recognize when all solutions of a given node are equivalent to solutions to the left of that node.

For any feasible solution x in node a of the tree $\mathcal{T}$, the branching history from the root node of $\mathcal{T}$ to a is needed in order to determine whether there is an equivalent solution to x that is found at a node to the left of a (to determine whether x is in the fundamental domain). This branching information is encoded in the vector M^a that ranks variables based on the order in which they were branched. Suppose that x_i was the first variable branched on at an ancestor of a (the variable chosen for branching at the root node). Index i , then, has rank “1” at node a and $M[i]^a = 1$. Similarly, if node j was branched on at the ancestor of node a with depth k in the tree, then j is assigned rank “ k ” at node a and thus $M[j]^a = k$. For the sake of completeness, variables that have not been branched on are given the rank $n + 1$. We can extend the idea of rank to work on subsets of I^n . For any set $S \subset I^n$, $M^a(S) = \{M^a(i) | i \in S\}$. Key theorem from Ref. 29 is that if $M^a(F_1^a)$ is not lexicographically minimal in the set $\text{orb}(M^a(F_1^a), \mathcal{G})$, then for no solution feasible at node a is in the fundamental domain. Thus, node a can be pruned by isomorphism if $M^a(F_1^a)$ is not lexicographically minimal in the set $\text{orb}(M^a(F_1^a), \mathcal{G})$.

The goal of isomorphism pruning is to determine when a node contains *only* solutions that are not in the fundamental domain. Unlike orbitopal fixing, there has been no attempt to use symmetry to separate those solutions in the fundamental domain from those that are not. As a result, isomorphism pruning may prune nodes much later in the

tree as would have been possible had the constraints defining the fundamental domain been included in the original problem formulation. However, there has been some effort in exploiting symmetry in order fixing variables in addition to pruning nodes. A powerful idea, called *orbit setting*, is to combine the variable fixing with symmetry considerations in order to fix many additional variables. For instance, if a variable can be set to zero as a result of any logical implication, then all variables sharing the same orbit can also be fixed to zero.

Orbital Branching

Orbital branching, discussed in Refs 30 and 31, is an intuitive way of exploiting the symmetry group $\mathcal{G}(\text{ILP})$ during branching decisions. The classic 0–1 variable branching dichotomy does not take advantage of the problem information encoded in the symmetry group. The presence of symmetry provides ways of strengthening both branching disjunctions and variable fixing algorithms. Symmetry can be exploited by fixing variables via symmetry considerations either at the node or during branching. Orbital branching fixes variables during branching. By using symmetry considerations to strengthen branching decisions, the affects of branching on a given variable are better known at the time the branching decision is made and, thus, results in better branching decisions. Orbital branching can be used as a stand-alone symmetry-breaking tool or in conjunction with other methods such as isomorphism pruning.

Let $\mathcal{G}^a$ be the symmetry group of the subproblem represented by node a in the branch-and-bound tree. Let $O = \{i_1, i_2, \dots, i_{|O|}\} \subseteq N^a$ be an orbit of the symmetry group $\mathcal{G}^a$. Given a subproblem a , the disjunction

$$x_{i_1} = 1 \vee x_{i_2} = 1 \vee \dots \vee x_{i_{|O|}} = 1 \vee \sum_{i \in O} x_i = 0 \quad (20)$$

splits the feasible region. In what follows, it is shown that for any two variables x_j and x_k with $i, j \in O$, the two children $a(j)$ and $a(k)$ of a , obtained by fixing respectively x_j and x_k to 1, have the same optimal solution value. As a

consequence, disjunction (20) can be replaced by the binary disjunction:

$$x_h = 1 \vee \sum_{i \in O} x_i = 0, \quad (21)$$

where h is an arbitrary element in O . Note that the additional variable fixings in Equation (21) can be done by the orbit-setting algorithm in isomorphism pruning and equivalent algorithms in constraint programming literature. Orbital branching can be extended to allow for branching on general disjunctions [32].

In addition to exploiting the symmetry group at the root node, $\mathcal{G}$, orbital branching can recognize and exploit symmetry that enters the problem as a result of the branching decisions. This method is similar to that of Ref. 33 for constraint programming. The results of Ref. 30, however, indicate that the time spent finding these new symmetries outweigh their benefits.

SYSTEM AVAILABILITY

DONALD P. GAVER
PATRICIA A. JACOBS
Department of Operations Research,
Naval Postgraduate School,
Monterey, California

OVERVIEW

All mechanical, electrical, nuclear power generation, propulsion, weapons systems, computer and data storage systems (both hard and software), communications, biological/medical, and many combinations thereof that are designed, manufactured and tested, operated and maintained using human skills, engineering, and scientific knowledge, *are subject to failure*. This means that at some point of time, a system becomes unable to perform the intended design function, or mission. *Reliability* is traditionally a probabilistic measure of the propensity of component, subsystem, or system (of systems) to satisfactorily perform a required designed performance function on, say, a civilian (consumer or government), or a military, or homeland security mission. This includes effectively and promptly responding to a natural disaster such as a hurricane, tornado, or earthquake. During the period of inability to perform, the item is said to be *not available* or *unavailable*. Often this propensity is quantified as a *conditional probability*, where the conditions include stressful aspects of the operational environment and usage. Note that it is not customary to include *vulnerability* to opponent action in measures of military or security system reliability, but the prevention and remediation responses to deliberate failure causation and those of failures from natural, including operator, causes are similar. In homeland security, vulnerability can be forestalled by instrumentation and personnel screening [1]. Many, even most, failed systems are subject to failure correction

or rectification, are *repairable*, which often requires a nonnegligible total *down time*, during which time interval they are completely or partially unavailable. Thus, an initial informal definition of *availability* can be an estimated probability that, at the moment of demand/need for a system's performance, it will furnish that service, and not be waiting for or being rectified/repaired/replaced. Field support of system availability and capability to accomplish a mission profile depends upon *sustainment resources*—personnel, diagnostic instrumentation, logistics/spare parts, tow vehicles, and so on. These must also be available when needed, and themselves be reliable.

It is often true that the failure propensity measure, or *hazard*, or *hazard rate*, of a component, subsystem, or system, $h(x)$, eventually increases with time or intensity of usage and “wear” or “age”, x , after being fielded. Hazard (rate) is defined as the conditional probability of failure of a system, given survival to operating age x , and conditional on past and present environmental conditions; biometric survival analysis is relevant here [2]. Typically, a new or modified/upgraded system is tested so as to identify and remove or reduce the effect of *design defects* or *failure modes*; during the early and operational testing period every attempt is made to induce the activation, thus exposure of, *design defects* or *failure modes*, that is, to *stimulate* occurrences of failures and remove their causes [3]. Some faults inevitably remain, and can be found later, desirably during routine scheduled maintenance. However, such maintenance can be unnecessary (time-scheduled maintenance is costly in time and resources, and may well find nothing, so wastefully decreases system availability and increases life cycle cost). It is currently thought to be desirable, and increasingly technically feasible, to identify and automatically track *system health* changes—failure-preceding or prognostic events (excess heat, undue vibration, wear of, say, tire treads, tires, engine oil condition,

etc.) that can signal an incipient failure and thereby suggest needed system design or operational changes before total, possibly catastrophic, failure can occur; periodic lubrication of civilian motor vehicles is a case in point. Annual physical checkups for humans is another. A specific potential payoff area is that of using aerothermodynamic signatures to predict fouling in gas turbines via sensing change in mass flow and adiabatic efficiency. Reduction of power output, and increase in fuel consumption can lead to degradation of compressor performance because of blade fouling and consequent roughness, and hence of gas turbine capacity [4]. The procedure for mitigating (“washing blades”) such conditions is known as *condition-based maintenance (CBM)*, and makes use of currently available automated embedded sensors, logistic assets, and training to conduct optimized CBM; hence CBM+. However, a CBM+ subsystem is itself subject to malfunction and failure, so false positive and false negative diagnoses must be anticipated and made rare in order for overall gains to be made. Thus the reliability/availability of CBM+ must itself be considered as part of the total system package.

Accelerated testing procedures are often used at an early (developmental) testing stage [5]. During the testing phases, both engineering and operational, it is intended, likely, and desirable to *find design faults and “fix” them*, so that they will not activate without adequate warning and cause mission-abortive events under active usage conditions. It is the usual objective to test and “fix” until time between failures during testing become a trend-free stable-in-time random process meeting specified criteria, often represented by evidence of a temporally stationary *time-between-successive-failures distribution*, with the further assumption that the time between failures are statistically independent (*iid random variables* = IIDRV, i.e., a renewal process [6]); see Gaver *et al.* [3], and several computer packages, such as Reliasoft (www.reliasoft.com). Frequently and without much validation, times to failure (measured from installation or repair termination to next failure) are assumed exponentially distributed, with the

mean value fixed—the so-called mean time between failures. Termed the “*exponential assumption*,” this is computationally convenient but worthy of critical scrutiny if possible. Appeal to lessons from analogous systems in similar usage environments is advisable.

Initial tests of a newly designed system typically reveal “infant failures” that should be removed before any approximate stability of times-between-failures occurs. The consequence of such removal is referred to as *reliability growth*, and it has been modeled and analyzed extensively, for example, by Crow [7,8], for example, in the software package Reliasoft; see Gaver *et al.* [3] for discussion of testing for growth using a sequential (run of successes) stopping rule; such testing is made more complex if the system performance is in sequential stages; failure of an early stage may mask the exposure of later stages, thus requiring longer tests so as to explore all stages for faults. After (*if*) there is evidence of failure time stochastic stability it is meaningful to speak of the *mean (operating) time between failures*; this is often specified as a reliability metric, but since systems are used to perform a task or mission, an estimate of the probability of mission success is usually more relevant, certainly if the item is a one-shot device or is usually quiescent in performance: a piece of ammunition or a communication system for emergencies. This can degrade or fail out right during idle periods, necessitating periodic inspections. Caution is required; justification for such a stable failure-time distribution must depend on actual data monitoring, and the currently appropriate particular distributional form (model) will depend on environmental conditions, including maintenance skill, and usage and environment; for example, operating times between successive failures for a particular equipment (surface motor vehicle, aircraft or helicopter-civilian or military) in the Arctic can be expected to differ from those operating under tropical, or hot, sandy, and dusty desert conditions.

Upon failure, some (but not all, e.g., expendable missiles and ammunition) system components are repaired; this requires

diagnostic and maintenance facilities and personnel, and logistics (spare parts); the system may then be again capable of performing designed-for functions. Repair or replacement is intended to restore original capability, or possibly upgrade (or in fact actually occasionally and unintentionally *downgrade*) system function. Preventive maintenance (PM), based on the observed or inferred/sensed physical condition of the system, may be used to ward off catastrophic failures or to halt prolonged degradation. As stated earlier, current attention is being focused on automated information-system-supported CBM, or *CBM+* (alternatively, integrated vehicle health management, *IVHM*). Such subsystems continuously monitor the “health condition” of various subsystems and provide warning of imminent malfunction/failure. If successful, such a capability should allow more operative mission hours, and shorter and fewer time-consuming and costly repairs. Success depends upon the trustworthiness of the *CBM+/IVHM* systems available [9–11]. Availability is enhanced under well-tuned *CBM+/IVHM*, since times between failures are lengthened and maintenance periods shortened.

This article considers that times or events between such system failures (during functional usage) are punctuated by periods of “down-time”, during which the system (copy or version thereof) is (i) awaiting maintenance, which may include moving, or being moved, to a repair facility, and awaiting the arrival of parts, instrumentation, and personnel; (ii) undergoing diagnosis of faults and subsequent maintenance actions; or (iii) awaiting further operational assignment (in idle standby); items may fail or degrade during such waiting/idle times, and so preliminary tests may aptly be performed prior to mission assignment: premission testing is often conducted, especially with aircraft and other platforms. This permits the detection of imperfect repair before the mission actually is in progress.

Availability issues also arise in the operation of modern networked computer systems [12]. Among the causes of unavailability of computer utilities such as *clouds* are service

interruption from hostile action: hacking and jamming. Service degradation by necessary security actions is also a performance or service inhibitor.

SPECIFIC DEFINITIONS

The (classical) system *operational availability* (A_0) *parameter* is a measure of the capability of a system to *begin* to perform a designed-for function or mission *on immediate “random” demand*. Nominally, this would imply that the system is in idle state (iii) above, but too long a sojourn of idleness (in “cold standby”) in a hostile environment can induce *startup unavailability which adds to down time*. *Mission availability*, measuring the capability of a system to perform its function from demand for service until mission termination is usually of far more operational significance than simple A_0 . The latter is too often treated—inappropriately—as “the long-run fraction of time” (or “constant probability”) that a component or system is “up” or completely mission capable at the time of demand for operation. In reality, such a constant value may not prevail; “the” value of A_0 may well change with time and usage, including the effect of maintenance variation between individual copies of a system design. Further, a system’s availability may be partial: for example, a multi-engine vehicle can still partially function if degraded by the loss of one out of several engines. However, loss of an engine or, one of several sensors, or a communication link sometimes allows a modified or limited version of the intended mission to proceed until a replacement is furnished. Consequently, availability need not be a binary instantaneous concept.

The object of this article is to describe methods in use for describing, measuring, testing, and improving *availability* and to provide cautionary comments similar to those above.

COMPONENT AND SYSTEM OPERATIONAL CLASSIFICATION

Engineered systems of all types are composed of numbers of components (“parts”),

subsystems, and entire systems designed to perform cooperative functions. Modern warfare has been said to be conducted by “systems of systems” (SoS). Health care systems and road and air traffic systems have the same SoS characteristics. Such systems operate efficiently and effectively according to correct design, manufacture, and usage especially if usefully guided by carefully conducting modeling, simulation, and limited tests. They are likely to fail or degrade with age and stress; some failure modes are mission and even life-threatening, and can occur with little warning. Hence condition-based monitoring/maintenance (CBM) and PM are required and invoked; time spent in such makes the entity temporarily mission unavailable, but is intended to provide greater overall net system mission availability.

Systems, and especially subsystems and components, can be roughly categorized as follows:

- *one-shot/disposable* (e.g., fuel, ammunition, missiles or mines, electronic components such as computer chips or screens, remote vulnerable sensors, etc.); *and/or*
- *repairable* (segmentally)—*replaceable* (e.g., failure-prone engines and control devices, vehicle chassis, computer hardware, elements of communication networks, etc.); an injured or wounded human can sometimes be included in this category, as being part of an entire system.

In many cases, a failed repairable system becomes less repairable as the system ages, the *particular item's* availability terminates, and it is replaced; the latter replacement can be a redesigned upgrade [3]. Alternatively, a downed military aircraft can become a “hanger queen”, and is cannibalized for spare parts; a desperate practice that is discouraged. Further, the pattern of component/system usage can vary: many items such as some sensors and alarm systems, and engines and generators are normally running or “hot” during a mission, so if failure occurs or becomes imminent, symptoms are quickly evident. Others are normally inactive

or “cold”, such as an idle aircraft parked on a flight deck, or a rescue vehicle.

Many systems are made up of complex assemblies or combinations of one-shot/disposable *and* repairable/replaceable subsystems: a vehicle or platform burns fuel and may fire ammunition, both disposable, but its chassis, propulsion, and steering and sensors, and communications are very often repairable/replaceable. Many vehicles operate in groups: convoys of trucks or small boats, task groups, aircraft squadrons, and so on; here the mission may involve all elements of the group, so the timely availability of such a subforce at a particular site can be spoiled if just one or a few of the member elements fails—the entire system may become mission-incapable, or unavailable if one or more of such elements fails, or is damaged by opponent action (when in military or homeland protection application), by environmental conditions (e.g., sandstorms), or by owner/user mishandling. The tendency for such to occur is enhanced when hostilities occur, and when the sustainment/support forces and logistics are overwhelmed and themselves unavailable.

MODELING AVAILABILITY

Modeling the availability of a system or an SoS is carried out to forecast or predict that system's condition to perform its mission. System availability has been characterized probabilistically or stochastically for many years; an initial classic is Barlow and Proschan [13], but aspects of repairable system availability go far back to Erlang, Khinchine, and to Palm in the 1930s and a further few decades, well summarized in Feller [14] as the “repairman problem” or a service system. See also Cox and Oakes [2] on survival analysis, essentially summarizing biological (e.g., animal, human) “reliability”. Failure-prone but repairable SoS resemble biological epidemics: failures of subsystems can stress, or infect, other subsystems that in turn can cause total system collapse if not quickly isolated and mitigated.

The simplest analytical model for a failure-prone but repairable system is the alternating renewal process (see, however,

practical cautions in the section titled “Overview”) [6,15]. Letting a sequence of up-times, $\{\mathbf{U}_i\}$, and a sequence of down-times, $\{\mathbf{D}_i\}$, be independent sequences of independent random variables with marginal distributions $F_U(u; \underline{\theta})$ and $G_D(v; \underline{\varphi})$, respectively, and $\underline{\theta}$ and $\underline{\varphi}$ representing parameters; then if $A(t)$ is the availability at time t , given that the subsystem starts at the beginning of an up period, $\mathbf{U}_1$, say, we have the backward recurrence renewal equation

$$A(t) = P\{\mathbf{U}_1 > t\} + \int_0^t P\{\mathbf{U}_1 + \mathbf{D}_1 \in dx\} A(t-x) \quad (1)$$

which can be solved numerically or in terms of Laplace–Stieltjes transforms. Basic renewal theory asymptotics [15, Chapter 11], shows that if $E[\mathbf{U}]$ and $E[\mathbf{D}]$ exist/are finite then

$$\lim_{t \rightarrow \infty} A(t) = E[\mathbf{U}] / (E[\mathbf{U}] + E[\mathbf{D}]) = A_o \quad (2)$$

the popular (often misused) operational availability. In cases in which the system must function throughout a mission of length M , a more informative measure is mission availability

$$A_m = A_o \frac{P\{\mathbf{U} > M\}}{E[\mathbf{U}]},$$

an asymptotic renewal theory result [15].

Complex systems, starting with series/tandem configurations, and extending to series/parallel/redundant combinations can be mathematically analyzed under the initially stated independence assumptions, and with these progressively relaxed.

STATISTICAL INFERENCE ON AVAILABILITY

If the simple assumption of mutually independent sequences of independent identically distributed (iid) up-time r.v.s $\{\mathbf{U}_i\}$, and likewise iid down-times $\{\mathbf{D}_i\}$, is (provisionally) acceptable, then alternating renewal theory shows that the long-run *point availability* is given by $A_o = E[\mathbf{U}] / (E[\mathbf{U}] + E[\mathbf{D}])$, provided expectations exist. A natural estimate of $A_o, \hat{A}_o = \bar{u} / (\bar{u} + \bar{d})$, where $\bar{u}$ and $\bar{d}$ are the

sample averages of up and down realizations; assuming no censoring [16] assesses confidence intervals for A_o using *jackknifing*, wherein the Logit transform of $\hat{A}_o$ is recomputed, omitting pairs of observations successively. The method is applied with good success to various redundant systems and several plausible distributional forms. An alternative would be the *bootstrap* [17]. A sensible (semi) nonparametric approach is the nonparametric bootstrap: resample from the empirical distributions of up- and down-times, provided that preliminary examination of the data does not wildly contradict iid assumptions [18]. In many applied situations, data may be insufficient to validate (or invalidate) such assumptions at all conclusively. System aging may decrease the mean time between failures and increase the mean system down-time. It may well be wise to adaptively smooth up- and down-time means, and employ these in the $\hat{A}_o$ formula or, often more appropriately, in $\hat{A}_m$ formula. Assumption checking is often carried out using engineering judgment, and should continue throughout system or SoS lifetime.

CONCLUSIONS

Availability quantitatively defines a system’s capability to respond to demand for its service. It combines reliability, the uninterrupted up-time to failure, and repair or down-time, during which the system cannot perform its mission. Simple parametric definitions of operational availability, $\hat{A}_o$, and mission availability, A_m , are given, and probabilistically modeled, and statistical inference procedures given.

Many more results are available from the references. For a general high-level overview, see Davis [19].

SYSTEMS IN PRACTICE

A number of applications in fields such as economics, engineering, higher education, and medical sciences consider units or components that are connected in some structure. The manner in which the components are connected as well as how each component is designed to function will determine if the system will function successfully or not. For example, when a package is delivered from point A to point B, it will typically go through different loading points in a systematic order. These loading points are the components in the system. Observing a failure at a loading point may result in delay in delivery of the package. Another example was considered in Ref. 1 regarding the different pathways that students pursuing a two-year degree can take. Each pathway is considered as a component and a student (in this case, the system) can take one and only one pathway. Ref. 2 assumed a committee with n members collectively making a decision on the acceptance of a project. Acceptance of a project depends on having k members agreeing to accept the project, where $k = 1, \dots, n$. The higher the value of k , the stricter the acceptance rule becomes. In the medical field, the survival of an individual depends on how organs are connected. The failure of a critical organ may result in the death of an individual.

A system that is commonly used in operations research and management science is called a *series system*. In a series system, components are connected in such a way that the failure of a single component results in system failure. From a different point of view,

a series system will function if and only if all components are functioning. A series system is also referred to as a *competing risks system*, since the failure of an individual (system) can be classified as one of n possible risks (component) that contribute to the individual's failure. An example of a series system is illustrated in Refs 3 and 4, where a series system of softwares is considered with the failure of a software (component) resulting in the failure of the system. Ref. 5 provides analysis of times to failures in the presence of competing risks with application to bone marrow transplantation for leukemia patients. Ref. 6 can be treated as an example of a series system, where an individual with a loan is the system of interest and the distinct reasons for complete loan repayment ahead of maturity date are the components connected in series. Finally, Bier *et al.* [7] and Hausken [8], among others, considered the optimal defensive strategy for a series system based on a trade-off between cost and security.

One of the goals in reliability is to ensure that at any given instant, we observe a functioning system with a high probability. The probability that the system is functioning is defined as the system reliability. In finding the system reliability, one needs to obtain the reliability of each individual component and take into account the manner in which the components are connected. In this article, we consider a series system and our main interest is to find the system reliability. In particular, we will focus on the situation where the reliability of each component is a function of the time to component failure.

SYSTEM RELIABILITY

Structure Function of a Series System

Let us consider a system of n components, where the state of a component can be classified as "functioning" or "failed." We can define a binary random variable X_i , for $i = 1, \dots, n$, as

$$X_i = \begin{cases} 1, & \text{if component } i \text{ is functioning,} \\ 0, & \text{if component } i \text{ has failed.} \end{cases}$$

The random variables $X_1, \dots, X_n$ are assumed to be mutually independent, that is, the failure of a component does not affect the probability of failure of any other component. We define the 0-1 vector $\mathbf{X} = (X_1, \dots, X_n)$ to be the state vector of a system. For any two vectors $\mathbf{X}$ and $\mathbf{Y}$, we define vector inequality to be $\mathbf{X} \leq \mathbf{Y}$ whenever $X_i \leq Y_i$ for all $i = 1, \dots, n$. In addition, $\mathbf{X} < \mathbf{Y}$, if $X_j < Y_j$ for at least one j and $X_k \leq Y_k$ for the remaining k components.

The state of a system, referred to as the *structure function* of the system, is a function that depends on the manner in which the individual components are connected and the state of each component. A system's structure function is denoted by $\phi(\mathbf{X})$ and takes a value 0 or 1, where

$$\phi(\mathbf{X}) = \begin{cases} 1, & \text{if the system is functioning,} \\ 0, & \text{if the system has failed.} \end{cases}$$

The structure function is said to be a non-decreasing function whenever $\mathbf{X} \leq \mathbf{Y}$ implies that $\phi(\mathbf{X}) \leq \phi(\mathbf{Y})$.

A primary interest in reliability is to consider systems where the action of replacing a failed component by a new component will not result in the system being "worse off." Moreover, it is of interest to examine a system where components are all deemed to be relevant to the system function. One can define a component i to be irrelevant if for all values of X_j , where $j = 1, \dots, n$ and $j \neq i$,

$$\begin{aligned} &\phi(X_1, \dots, X_{i-1}, 0, X_{i+1}, \dots, X_n) \\ &= \phi(X_1, \dots, X_{i-1}, 1, X_{i+1}, \dots, X_n). \end{aligned}$$

In other words, changing the status of an irrelevant component from failed to functioning will not have any effect on the status of the system. Systems that do not contain irrelevant components and where the structure function is nondecreasing are called *coherent systems*. For any coherent system with n components, its structure function can be bounded by

$$\prod_{i=1}^n X_i \leq \phi(\mathbf{X}) \leq 1 - \prod_{i=1}^n (1 - X_i). \quad (1)$$

A more detailed discussion of coherent systems is given in **Coherent Systems**. For an in-depth treatment of coherent systems, the reader is referred to the monographs by Barlow and Proschan [9] and Gnedenko *et al.* [10].

A series system is an example of a coherent system. It is defined to be a system that functions if and only if all components are functioning. From the point of view of a failed component, a series system fails as soon as one component has failed. Thus, the structure function of a series system is

$$\phi(\mathbf{X}) = X_1 X_2 \cdots X_n = \prod_{i=1}^n X_i. \quad (2)$$

Note that Equation (2) is the lower bound of the structure function of any coherent system given in Equation (1). On the other hand, the upper bound in Equation (1) is the structure function of a parallel system (see **Parallel Configurations**). Since the entries of $\mathbf{X}$ are all binary, the structure function of a series system can be written as $\phi(\mathbf{X}) = \min(X_1, \dots, X_n)$. Figure 1 shows a series system with three components.

As an illustration, consider a series system with $n = 4$ components where component 1 has failed, while the remaining $n - 1 = 3$ components are functioning. Thus, the state vector is $\mathbf{X} = (X_1, X_2, X_3, X_4) = (0, 1, 1, 1)$, which results in $\phi(\mathbf{X}) = \min(0, 1, 1, 1) = 0$. On the other hand, if all components are functioning, then $\phi(\mathbf{X}) = \min(1, 1, 1, 1) = 1$. Clearly, $\phi(\mathbf{X}) = 0$ whenever $X_i = 0$ for some i . To show that the series system is a coherent system, we need to consider two state vectors $\mathbf{X}$ and $\mathbf{Y}$ such that $X_i = 0$ for some $i = 1, \dots, 4$, while $Y_j = 1$ for all $j = 1, \dots, 4$. In other words, $\mathbf{X} < \mathbf{Y}$. From Equation (2), it follows that $\phi(\mathbf{X}) \leq \phi(\mathbf{Y})$, which means that ϕ is a nondecreasing function. In addition, it is easily seen that a series system with state vector $\mathbf{Y} = (1, 1, 1, 1)$ will fail as soon as one

Figure 1. Diagram for a series system with three components.

component fails. Hence, each component in a series system is relevant. Thus, a series system is coherent.

Reliability of a Series System

Suppose a series system is observed up to an instant of time t . Let $X_i(t)$ be the state of component i at time t and $\mathbf{X}(t) = (X_1(t), \dots, X_n(t))$ is the resulting state vector. Let $p_i(t) = P\{X_i(t) = 1\}$ be the probability that the i th component is functioning at time t and suppose $\mathbf{p}(t) = (p_1(t), \dots, p_n(t))$. We define

$$h(\mathbf{p}(t)) = E[\phi(\mathbf{X}(t))] = P\{\phi(\mathbf{X}(t)) = 1\}$$

to be the reliability of the system at time t .

From Equation (2) and the fact that $X_i(t)$ is a 0-1 variable, the structure function of a series system can be expressed as

$$\phi(\mathbf{X}(t)) = \begin{cases} 1, & \text{if } X_i(t) = 1 \text{ for } i = 1, \dots, n, \\ 0, & \text{if at least one } X_j(t) = 0. \end{cases}$$

Since $X_1(t), \dots, X_n(t)$ are independent random variables, the reliability of a series system is

$$\begin{aligned} h(\mathbf{p}(t)) &= P\{X_1(t) = 1, \dots, X_n(t) = 1\} \\ &= P\{X_1(t) = 1\}, \dots, P\{X_n(t) = 1\} \\ &= \prod_{i=1}^n p_i(t). \end{aligned} \quad (3)$$

TIME-DEPENDENT SYSTEM RELIABILITY

Survival Function for a Series System

We will now consider a series system with n components, where the failure of a component depends on how long the component has been in use. Let T_i be the time to failure of component i and we assume that T_i can be modeled via the probability density function $f_i(t; \theta)$, parameterized by θ . We will assume that $T_1, \dots, T_n$ are independent random variables. From Ref. 11, the reliability of component i is defined to be the probability that the component survives past time t . This is also referred to as the *survival function* and is expressed as

$$S_i(t; \theta) = P\{T_i > t\} = \int_t^\infty f_i(u; \theta) du. \quad (4)$$

When dealing with failure of components, an important function to consider is the hazard function $h_i(t; \theta)$, which can be interpreted as the amount of risk of a component. In terms of the probability density function and the survival function, the hazard function can be written as

$$\begin{aligned} h_i(t; \theta) &= \lim_{\Delta t \rightarrow 0} \left[\frac{S_i(t; \theta) - S_i(t + \Delta t; \theta)}{\Delta t} \right] \\ &\times \frac{1}{S_i(t; \theta)} = -\frac{S'_i(t; \theta)}{S_i(t; \theta)} = \frac{f_i(t; \theta)}{S_i(t; \theta)}. \end{aligned} \quad (5)$$

By noting that $\frac{d}{dt} S_i(t; \theta) = -f_i(t; \theta)$, the hazard function and the survival function are related by $h_i(t; \theta) = -\frac{d}{dt} \log S_i(t; \theta)$.

Let Y be the random variable associated with the system lifetime and $S(y; \theta)$ be the system reliability. The corresponding density function, cumulative distribution function, and hazard function of the system lifetime are $f(y; \theta)$, $F(y; \theta)$, and $h(y; \theta)$, respectively. In terms of the density function and cumulative distribution function, the hazard function is

$$h(y; \theta) = \frac{f(y; \theta)}{S(y; \theta)}. \quad (6)$$

From Equation (2), the system lifetime for a series system can be expressed as $Y = \min(T_1, \dots, T_n)$. Using Equation (4), the system reliability is equal to

$$\begin{aligned} S(y; \theta) &= P\{Y > y\} = P\{\min(T_1, \dots, T_n) > y\} \\ &= P\{T_1 > y, \dots, T_n > y\} = \prod_{i=1}^n P\{T_i > y\} \\ &= \prod_{i=1}^n S_i(y; \theta). \end{aligned} \quad (7)$$

It follows that the density function of the system lifetime of a series system is

$$f(y; \theta) = -\sum_{i=1}^n S'_i(y; \theta) \left[\prod_{\substack{j=1 \\ j \neq i}}^n S_j(y; \theta) \right].$$

The hazard function is obtained by substituting the appropriate expressions for $f(y; \theta)$ and $S(y; \theta)$ into Equation (6).

Let us consider the special case when the component lifetimes are also identically distributed. In other words, the density function and survival function of the i th component are $f_*(t; \theta)$ and $S_*(t; \theta)$, respectively. From Equation (7), the system reliability simplifies to

$$S(y; \theta) = [S_*(y; \theta)]^n$$

and the corresponding density function is

$$f(y; \theta) = n f_*(y; \theta) [S_*(y; \theta)]^{n-1}.$$

Exponential Lifetimes

We will now consider the case when the individual component lifetimes are assumed to be exponentially distributed. Exponential lifetimes for a software were considered in Ref. 12, where the mean lifetime depends on the residual number of defects remaining in the software as well as the failure rate contributions of each software. Exponential lifetimes were also considered, among others, by Basu *et al.* [13] in the area of market research; Osborne and Severini [14] in goodness-of-fit testing; and Özekici and Soyer [15] and Agustin and Agustin [16] in the area of software reliability.

Let T_i be the lifetime of component i that is assumed to be exponentially distributed with density function

$$f_i(t; \theta_i) = \theta_i \exp\{-\theta_i t\}, t > 0.$$

Thus, the expected lifetime of component i is $\mathbf{E}(T_i) = 1/\theta_i$. Using Equations (4) and (5), the survival function and hazard function of T_i are

$$S_i(t; \theta_i) = \exp\{-\theta_i t\}, \quad t > 0 \quad \text{and}$$

$$h_i(t; \theta_i) = \theta_i, t > 0,$$

respectively. Thus, the hazard function of the component lifetimes is constant.

Let $Y = \min(T_1, \dots, T_n)$ denote the series system lifetime and let $\theta = (\theta_1, \dots, \theta_n)$ represent the parameter vector of interest. It follows from Equation (7) that

$$S(y; \theta) = \prod_{i=1}^n \exp\{-\theta_i y\} = \exp\left\{-y \left(\sum_{i=1}^n \theta_i\right)\right\}.$$

Moreover, the density function of Y is

$$\begin{aligned} f(y; \theta) &= \sum_{i=1}^n \theta_i \exp\{-\theta_i y\} \left[\prod_{\substack{j=1 \\ j \neq i}}^n \exp\{-\theta_j y\} \right] \\ &= \left[\sum_{i=1}^n \theta_i \right] \left[\exp\left\{-y \left(\sum_{i=1}^n \theta_i\right)\right\} \right]. \end{aligned}$$

Consequently, we note from Equation (6) that

$$h(y; \theta) = \sum_{i=1}^n \theta_i.$$

One can easily see that the system lifetime Y is exponentially distributed with mean $\mathbf{E}(Y) = [\sum_{i=1}^n \theta_i]^{-1}$.

When the component lifetimes are also identically distributed, that is, $\theta_i = \theta$ for $i = 1, \dots, n$, then the above functions take simplified forms. The system reliability and density function of the series system lifetime become

$$S(y; \theta) = \exp\{-y(n\theta)\} \quad \text{and}$$

$$f(y; \theta) = (n\theta) \exp\{-y(n\theta)\},$$

respectively, which results in the hazard function

$$h(y; \theta) = n\theta.$$

Hence, the series system lifetime is exponentially distributed with mean $\mathbf{E}(Y) = (n\theta)^{-1}$.

Pareto Lifetimes

We now consider the scenario where the component lifetimes do not have constant hazards. In particular, we will consider a family of monotone hazard functions of the form

$$h_i(t; \alpha_i, \lambda_i, \phi_i) = \alpha_i + \frac{\lambda_i}{t + \phi_i}, \quad (8)$$

with $\alpha_i > 0$, $\phi_i > 0$, and $\lambda_i \geq -\alpha_i \phi_i$. This family of hazard functions, known as a *Pareto family*, was considered in Ref. 17 when modeling the situation, where the failure of an

individual due to a certain disease depends on events that transpired in the individual's life, such as surgery. A similar form of the hazard function in Equation (8) for examining the failure of a software was also used in Ref. 18. This work was extended in Ref. 19 by assuming that the lifetime of softwares connected in series has hazard function similar to Equation (8), with the additional assumption that the value of one of the parameters depends on the number of system failures observed.

From Equation (8) and using the fact that $S_i(t; \theta) = \exp \left\{ - \int_0^t h_i(u; \theta) du \right\}$, the survival function of the i th component is

$$S_i(t; \alpha_i, \lambda_i, \phi_i) = \exp\{-\alpha_i t\} \left(1 + \frac{t}{\phi_i}\right)^{-\lambda_i}.$$

Note that if $\lambda_i = 0$ for $i = 1, \dots, n$, then the component lifetimes become exponentially distributed. Thus, the case considered in section titled "Exponential Lifetimes" becomes a special case of Pareto lifetimes.

Let $\theta = (\alpha_1, \lambda_1, \phi_1, \dots, \alpha_n, \lambda_n, \phi_n)$ denote the parameter vector and $Y = \min(T_1, \dots, T_n)$ represent the lifetime of a series system with n components. Using Equation (7), we can find the survival function of Y to be

$$S(y; \theta) = \left[\exp \left\{ - \left(\sum_{i=1}^n \alpha_i \right) y \right\} \right] \times \left[\prod_{i=1}^n \left(1 + \frac{y}{\phi_i} \right)^{-\lambda_i} \right].$$

As a special case, if $\phi_i = \phi$ for $i = 1, \dots, n$, the survival function of Y becomes

$$S(y; \theta) = \left[\exp \left\{ - \left(\sum_{i=1}^n \alpha_i \right) y \right\} \right] \times \left[\left(1 + \frac{y}{\phi} \right)^{-\sum_{i=1}^n \lambda_i} \right],$$

which implies that the system lifetime is Pareto with parameters $(\sum_{i=1}^n \alpha_i, \sum_{i=1}^n \lambda_i, \phi)$. In addition, if $\alpha_i = \alpha$ and $\lambda_i = \lambda$ for $i = 1, \dots, n$, that is, the component lifetimes are independent and identically distributed, then

$$S(y; \theta) = \exp\{-(n\alpha)y\} \left(1 + \frac{y}{\phi}\right)^{-n\lambda},$$

which implies that Y is Pareto with parameters $(n\alpha, n\lambda, \phi)$.

SYSTEMS MODELING TO INFORM DRUG POLICY

JONATHAN P. CAULKINS
Heinz College, Carnegie Mellon
University, Pittsburgh,
Pennsylvania

The production, distribution, use, and control of illegal drugs generates enormous social costs. In countries that have recently quantified the annual burden, the estimates are very large: \$1.4 billion in Canada [1], \$2.3 billion in France [2], \$6 billion in Australia [3], £15.4 billion in the United Kingdom [4], and \$180 billion in the United States [5].

Not surprisingly, there is energetic debate concerning how best to control drug use and its related consequences. Operations research/management science (OR/MS) has made important contributions to this debate.

This article does not attempt a comprehensive review. Rather, it highlights sample contributions from some classic studies, with additional references for those who want to dig deeper. The goal is to offer a flavor of how OR/MS perspectives can contribute to this important policy debate, not to provide a comprehensive resource for drug policy analysts.

The focus is on analysis that supports “systems understanding” and “strategic” drug policy choices. System understanding is valuable because the drug “system” is complex, and unintended consequences of interventions are common. Drug policy at the strategic level can be viewed as a resource allocation problem with resources divided across programmatic areas (source country control, interdiction, prevention, etc.) in order to optimize some social welfare function.

The discussion is organized into sections that highlight parallels between traditional interests of OR/MS and issues that are important when modeling drug policy. Specifically, the drug-related topics with their conventional OR/MS analogs in parentheses are modeling initiation (new product adoption),

demand (Markov modeling), supply (production and distribution), supply shocks (disequilibrium modeling), and policy evolution over the course of a drug epidemic (dynamic optimization).

Each section can be seen as addressing part of an integrated dynamic optimization problem. If we let $I()$ denote initiation and $\mathbf{X}()$ denote the current number of drug users, then the first two sections describe how initiation, $I()$, and endogenous growth, $g()$, depend on the state ($\mathbf{X}$) and controls ($\mathbf{u}$). So suppressing the time argument, t , for clarity, we may describe the evolution of drug use by

$$d\mathbf{X}/dt = g(\mathbf{X}, \mathbf{u}) + I(\mathbf{X}, \mathbf{u}).$$

Intersecting at any given time, the resulting demand, $Q_D(\mathbf{X})$, with a model of supply $Q_S(\mathbf{X}, \mathbf{u})$ modulated by possible supply disruptions, $\varepsilon(\mathbf{u})$, discussed in the third and fourth sections, yields a condition that determines the market clearing price, p :

$$Q_D(\mathbf{X}; p) = Q_S(\mathbf{X}, \mathbf{u}; p) + \varepsilon(\mathbf{u}).$$

This price in turn modifies the epidemic dynamics. That is, the system dynamics depend on the price, p and so might be more properly written as

$$d\mathbf{X}/dt = g(\mathbf{X}, \mathbf{u}; p) + I(\mathbf{X}, \mathbf{u}; p).$$

The final section addresses the policy question, what time-varying control vector $\mathbf{u}$ influences this dynamic system to evolve in the “best” possible way, for some definition of best.

MODELING DRUG INITIATION AS NEW PRODUCT ADOPTION

Bass’ [6] classic model initiated a significant literature on new product adoption. (See also the section titled “Forecasting” in this encyclopedia, for forecasting and diffusion models.) The key feature of Bass’ model was

that while some people (innovators) might spontaneously decide to use a new product, others (imitators) do so by following the lead of people who were already using the product. Hence, an important subset of product initiation could be modeled as being proportional to the current number of users of the product times the number of people who had not yet started using it.

Modeling “initiation” as being proportional to the product of people who are currently in the population of interest (“infected”) times the number who could join (“susceptibles”) also has a storied history within so-called *susceptible–infected–recovered* (SIR) models of the spread of contagious diseases [7]. Indeed, people have long referred to the ebb and flow of drug use as “epidemics” because current users tend to “recruit” new users [8,9].

Attempts to mathematically model drug problems draw inspiration from both of these literatures. The metaphor of infectious spread is particularly potent for illegal drugs because typically the other user is not only the inspiration for initiation, but also the supplier, since prospective users cannot simply go to a store to obtain drugs. Furthermore, product illegality stifles advertising, so word-of-mouth diffusion of product information is more important than it is for most conventional goods [10].

The regularity of illegal drugs’ new product adoption trajectories is striking. Figure 1 illustrates this with retrospective self-report

data provided by 388,617 respondents to the 1999–2005 US National Household Surveys on Drug Use and Health. Respondents who had used any of these nine illegal drugs [marijuana, cocaine, crack, heroin, methamphetamine, hallucinogens, lysergic acid diethylamide (LSD), phencyclidine (PCP), and Ecstasy] were asked in which year they started using that drug. Popularity of the drugs varies considerably (many more people have tried marijuana than heroin), so the series were normalized to make their initial peak level be 100%. Similarly, some drugs became widely available earlier than others (marijuana and heroin in the 1960s, cocaine in the 1970s, and Ecstasy even later), so the normalized initiation plots were time shifted to align the convex growth part of their “S-curves.”

Plotting all nine lines creates a graph that is hard to read because the lines overlap (figure not shown), but the overlap is exactly the point. Despite enormous differences in price, dependence potential, neural pathways affected, and so on, all nine substances followed similar initiation trajectories after normalization and time shifting. Figure 1 shows this commonality by plotting the average of the nine normalized trajectories along with dotted lines showing the average ± 1 standard deviation. Where the dotted lines are close to each other, all nine substances followed very similar trajectories. Postpeak there was some variability. Initiation dropped off dramatically for some drugs (Ecstasy and PCP) and

Figure 1. Average (± 1 std dev) across nine drugs of initiation trajectories in the US. After normalizing so peak initiation = 100% and time shifting to align their stages of rapid growth.

substantially for others (heroin and cocaine), but much less so for a few (e.g., hallucinogens). However, in the early growth stages of the epidemics, there was very little variation; initiation trajectories were very similar for all drugs suggesting that common “marketing” characteristics trump “pharmacological” factors when trying to understand this spread.

Another empirical regularity observed in US cocaine data is that the “infectivity” of current light users is inversely related to the ratio of current heavy to current light users [11]. That is, word of mouth seemed to work “best” as an initiation promoter when there were lots of light users relative to the number of heavy users.

Musto [12] offers a feasible hypothesis for why this should be so. The explanation depends on the fact, elaborated below, that drug use progresses through stages. Although there is a spectrum of intensities of use, much is gained simply by differentiating between “light users” who have initiated recently and are typically happy with their drugs and “heavy users” who may have escalated to drug dependence and are a visible reminder of the dangers of drug use.

As Kleiman [13] notes, early in a drug epidemic, most users are light users because they have not had time to escalate to dependent or problematic use. Since most of the current users are experiencing no problems, the drug has a relatively benign reputation. That benign reputation makes the drug attractive to nonusers, so the nonusers are likely to initiate when given the opportunity. This positive feedback from current light users to new initiates leads to rapid growth in initiation.

Over time, some of the original users escalate to heavy use, but news of their struggles is lost amidst the burgeoning sea of relatively happy light users. Eventually, though, either enough people escalate to heavy use or the rapid growth in initiation is tempered by exhaustion of the pool of susceptibles, and the proportion of current users who are experiencing problems begins to grow. When that happens, the drug begins to be seen as dangerous, which deters some potential initiates. As the inflow of new light users

ebbs, the total number of light users falls because people who never escalate typically do not use a drug like cocaine for more than a few years [11]. This further increases the proportion of dependent users, which in turn intensifies the drug’s negative reputation, further undercutting initiation. Thus, a negative feedback loop is established, and initiation is restricted to the subset of the population who are not deterred by the drug’s negative reputation. (Eventually, the drug’s reputation and initiation may bounce back somewhat from the nadir induced by the “bulge” in dependent drug use that comes a few years after the peak in light use.)

Models that build on such dynamics [14–17] have achieved strong fits to cocaine’s historical data by adding a reputational feedback term that multiplicatively modifies initiation. A typical form of the reputational adjustment might be

$$\text{Reputational adjustment} = (f + (1 - f) \times \exp(-qH/L)),$$

where f and q are the positive constants and H , L are the respective numbers of heavy and light users. (Early models set $f = 0$, but now it appears that overstates this “Musto dynamic”.) Almeder *et al.* [18,19] extended this formula by looking at a family of age-distributed models in which this reputational feedback also depends on the relative and absolute ages of current and potential users. To caricature, a 16-year-old’s interest in trying a drug may increase if a lot of 19-year-olds use the drug, but decrease (or at least not go up as much) if people of the teen’s parents’ generation commonly use it.

State dependence of the “infectivity” of current users is an intriguing extension of the classic Bass and SIR models [20]. For new product adoption of consumer electronics or psychoactive drugs, the probability an opportunity to initiate leads to an actual initiation may depend on how popular the product is. This idea makes a certain intuitive sense. If a friend suggests trying a drug or a new gadget that few others use, you might be more skeptical than if the drug or gadget is popular. The opposite may be true for certain fashion goods: in as much as conspicuous

consumption of an exclusive good signals status, a product already in widespread use might be less, not more appealing.

Wallner [21] and Caulkins *et al.* [22] explored this possibility for drug use models parameterized for both, the US and Australia. They find that feedback from the general prevalence of use to the “infectivity” of current users creates nonlinear dynamics that can greatly enrich the range of possible system behaviors. Notably, state-dependent infectivity can create multiple equilibria separated by “tipping points.” Around those tipping points enforcement (in the case of drugs) and advertising (in the case of conventional goods) may be particularly valuable if it can tip the system from a trajectory approaching an undesirable equilibrium over onto another trajectory approaching the more desirable equilibrium (the low use equilibrium for drugs, or high use for electronics).

To summarize, drug initiation can be modeled successfully with tools from the literatures on new product adoption and infectious disease transmission. This shocks some people in the addictions field, but actually makes perfect sense. The psychopharmacological characteristics of a substance cannot possibly play a direct role in decisions to initiate for the simple reason that before someone initiates, the drug has not entered the bloodstream or the brain. So, any peculiar effects stemming from the drug’s intoxicating or dependence-inducing potential are not yet relevant. We turn next to modeling the dynamics of ongoing consumption by existing users.

“STOCKS AND FLOWS” OR MARKOV MODELS OF DRUG DEMAND

OR/MS has long used a discrete set of states to represent the state of a system; for instance, a queueing model might define the state as the number of customers in the system. Estimating the rates of transition from one state to another allows one to explore the system’s steady-state properties and model the transient behavior as well. (See also the sections titled “Stochastic Processes” and “Queueing Theory and Queueing Networks”

on Markov chains and queueing models, in this encyclopedia.) Demographic models apply the same principle at a population level, with boxes (states) representing the number of people in various life situations (e.g., being an employed 30-year-old), with arrows representing flows of people from one state to another.

These same principles have proved enormously useful in drug policy to model both individual level trajectories or “careers” of drug use and also to model the aggregated evolution of a drug “epidemic.” Without the OR/MS mindset, people often track just the total number of past-year users, without adequately differentiating between types of users, and/or view annual prevalence estimates as a series of still pictures and not a continuous process that happened to be sampled at discrete intervals.

A number of early “systems dynamics” models had been produced over time [23–26], but in the early 1990s, Everingham and Rydell [27] of RAND’s Drug Policy Research Center made a pioneering breakthrough. They observed that much of the historical dynamics of the US cocaine epidemic could be described through a simple model that differentiated between only two types of users: “light users” who have initiated recently and are typically happy with their drug use and “heavy users” who have escalated to drug dependence and are a visible reminder of the dangers of drug use. Caulkins *et al.* [11] showed that the same model with slightly updated parameters continued to have great explanatory power a decade later, even though the data gathered in the intervening decade reflected a greatly changed epidemic.

Figure 2 describes the Everingham and Rydell model [27] with typical parameter values for a “hard drug” based on Caulkins *et al.* [11] and other more recent work.

This simple model reflects a number of crucial insights. For one, most (roughly 5 in 6) initiates do not escalate to heavy or dependent use. However, those who do escalate remain in that heavy or dependent use state for many years. In Fig. 2, $1/g = 12.5$ years, but values of g as low as 0.05 are common, implying an average dwell time in dependent use as long as 20 years. When

Figure 2. Everingham and Rydell's [27] light and heavy user model with flow rates updated by Caulkins *et al.* [11].

Everingham and Rydell's work [27] first appeared, audiences knew that opiate dependence could last in excess of a decade [28], but most were skeptical that cocaine dependence would last as long. (Whereas heroin addicts develop a certain routine, stimulant abuse is often characterized by bingeing, with use becoming all-engrossing until the user runs out of money. It was presumed by some that such behavior could not be sustained for many years.) Unfortunately, time has proven Everingham and Rydell's model correct; cocaine abuse is now thought of as a chronically relapsing condition despite the periods of abstinence or reduced use between binges.

The persistence of dependent use has a crucial implication for the value of what might otherwise seem to be relatively ineffective treatment interventions. In the past, the goal of treatment was to increase the out-flow rate from heavy or dependent use, and it appeared to be singularly ineffective at that goal. Relapse rates on the order of 80% were widely reported, and taxpayers became reluctant to "waste" their money on programs with such high failure rates.

Everingham and Rydell [27] looked into this issue from a systems perspective. Definitive data on treatment effectiveness were not and still are not available [29]. However, a simple calculation drawing on the model shows that, a treatment program with an 80% relapse rate can still be a terrific investment from the taxpayers' perspective.

Suppose that 80% of people enter a treatment program relapse, but 20% cease or substantially reduce their consumption in the

long run. Since from Fig. 2 we might expect something like 8% to have quit even without treatment, we might suppose that treatment led 12% of the admits to cease use. Their residual career of use could have been on the order of 10 or more years, suggesting a reduction of 1.2 person-years of dependent use. Furthermore, most (perhaps 80%) of the people cease or substantially reduce use during the 3 months (roughly) they are in treatment; so the total reduction might be closer to 1.5 person-years of use.

Social costs per person-year of dependent use vary with individual circumstances (notably, what proportion of drug purchases are financed by crime), but a figure of \$25,000 per year is not unreasonable. (For cocaine, the figures might be 120 g consumed per year with an average social cost of \$215 per gram consumed [30].) This suggests that treatment programs with 80% relapse rates could still generate social benefits of the order of $1.5 \times \$25,000 = \$37,500$ per person treated, vastly exceeding the average cost of \$2000–3000 per treatment admission. (The average cost per admission is so low because so many people drop out very quickly.) Indeed, programs that induce even 1 in 100 of those admitted to quit use permanently could be cost-effective.

It is simply not known what the exact parameters for such a calculation are, and they no doubt vary by country, drug, and type of user. Nevertheless, two conclusions can be drawn. First, if treatment is effective for even a minority of users, then it is probably cost-effective in the sense of averting more

social costs than it takes taxpayer dollars to subsidize it. Second, the performance metric used to evaluate treatment matters mightily. A treatment intervention that does very poorly when judged in terms of abstinence rates could still offer taxpayers an economical way of reducing social costs, including costs borne by nonusers, such as those associated with drug-related crime and violence. On the other hand, even treatment on demand [31] will not necessarily quickly eliminate most drug use [32,33].

Everingham and Rydell's simple two-state model has been extended in various ways. We mention just one. Kaya *et al.*'s [34] analysis of Australian heroin data shows that the number of people quitting heroin is highly correlated over time with the number initiating, presumably because the modal career of use is very short. Essentially for all illegal drugs, almost half of the people who try the drug report using it less than a total of 12 times in their lifetime. Furthermore, there was some tendency for initiation to oscillate up and down within a period of a few years. Also, Marotta [35] and Preti *et al.* [36] observe fairly high frequency oscillations in the number of heroin overdoses in Italy, and longer term oscillations have been observed for many drugs, including alcohol. Caulkins *et al.* [37] extend Everingham and Rydell's *LH* model to include two additional states. One is a very brief initial state from which users either progress to ongoing nondependent use (akin to the *L* state in Everingham and Rydell's model) or, if they do not like the drug, they quit. Those who quit more or less immediately are assumed to tell their peers that the drug is not particularly appealing, creating a negative feedback on initiation. However, inasmuch as these early quitters were never engrossed in the drug culture, they and their cautions are assumed to dissipate rather quickly. This four-state structure creates the possibility for simultaneous cycling on two different timescales (fast and slow). The resulting model displays sensible, but highly sensitive dependence on certain parameter values, with modest changes pushing the model through regions where its behavior is stationary, cyclic, quasi-periodic,

and chaotic. The model reveals that if different drugs have even modestly different attributes in terms of escalation lags or probabilities, strength of reputational feedback, and so on, that could translate into very different epidemic behaviors at the macrolevel.

To summarize, state-transition models of drug use have found wide application, not only for illegal drugs such as heroin [38,39], but also for tobacco [40,41] and it remains a promising area for further research.

MODELING THE SUPPLY CHAIN FOR ILLEGAL DRUGS

Medical and public health research focuses on drug use, but systems perspectives must also encompass drug supply. Modeling production and distribution is of course another area to which operations research has contributed. (See also the section titled "Supply Chain Management" in this encyclopedia.)

Building on Kennedy *et al.* [42], Childress [43,44] and Dombey-Moore *et al.* [45] developed descriptive systems models of the drug production and distribution chain from the source to the street. This foundation has been elaborated by many authors (e.g., Anthony and Fries [46]), but the essential observation for the typical drug is that there are several distinct stages of processing in the source country. Then, the finished product is moved across international borders where it is distributed domestically through a multilayered domestic distribution network, changing hands perhaps five or six times between import and final sale to the user [47], with prices increasing enormously as the drugs move down this distribution chain [48].

The standard paradigm for understanding why price markups are so large is Reuter and Kleiman's [49] "risks and prices" model. In it, enforcement acts like a tax, driving up the cost of distributing drugs. Since dealers distribute drugs to make money, they are assumed to pass these costs along to users in the form of higher prices. Contrary to what was once believed, there is clear evidence that drug use does respond to changes in price. Just as with other consumer goods, higher prices suppress current use (the "conditional elasticity") and also affect how many

people use (the “participation elasticity”). See Grossman [50] for a review of literature on the price responsiveness of drug use.

The risks and prices model raises the question, which types of enforcement are best in the sense of imposing the greatest costs on drug suppliers per million taxpayer dollars spent (or per some other metric, such as per person imprisoned)?

Drawing on the foundational work just described, Rydell and colleagues [32,33] developed one of the most frequently cited “systems analyses” of the relative effectiveness of different broad strategies for controlling drug use, in this case US cocaine use. Four strategies were considered: treating heavy cocaine users and three types of supply control programs (interventions in source countries, interdiction between the source countries and the United States, and law enforcement against drug suppliers operating within the United States).

The model assumed that the market was in dynamic equilibrium, so that each year suppliers’ revenues compensated them for all of the costs of business, including normal profits and monetary compensation for non-monetary risks of enforcement and violence. The model traced the evolution of the market over a 15-year planning horizon, as changes in demand and supply shifted the equilibrium from year to year. The supply model was multilayered and tracked separately the market prices and quantities in source countries, in transit, and within the United States, while factoring in both seizures and the markups needed to compensate for the risks of moving the drugs from one level to the next.

The demand at any given time had modest price responsiveness, and in addition prices influenced initiation, escalation, and cessation flows. So the price increase in a year would reduce the number of users in the following year.

The model led to a number of insights. For example, while it is cheaper for authorities to seize drugs closer to the source, it is also cheaper for the drug suppliers to replace drugs lost at those market levels. Indeed, as one moves down the distribution chain, the value of the drugs rises faster than does the difficulty of seizing them. As a result,

the “tax” imposed by enforcement seizures is actually stiffer within the United States than it is further upstream, in the sense that the costs imposed on suppliers is greater per million US taxpayer dollars spent. The overall model of enforcement included many factors besides drug seizures (including arrests, imprisonment, avoidance costs, and seizure of nondrug assets), but the same intuition holds over all. As long as the costs are passed down the distribution chain one-for-one (the so-called *additive model of price transmission*), enforcement can impose more damage on suppliers’ cost structure per million taxpayer dollars spent when it operates within the United States than it can when it operates abroad, particularly in source countries.

Within US borders, the risks and prices model has the feel of an arms race. If enforcement can impose enough cost on the suppliers per taxpayer dollar spent, it could be cost-effective. Everingham and Rydell [27] and most subsequent analyses [51,52] find that it is costly to fight this arms race once a market has matured. A mature distribution network is robust because of its many lateral linkages, independent paths, and the ability to expand quickly the capacity of individual arcs to compensate for arcs or nodes that have been removed by enforcement.

Furthermore, a concern with using enforcement to drive up drug prices is that high prices might increase crime even if they reduce use. Most drug-related crime is “economic-compulsive” (committed to obtain money to buy drugs) or “systemic” (arising from drug selling, e.g., punishment for nonpayment) and so is driven primarily by drug spending. Crime related to intoxication or use, called *psychopharmacological drug-related crime*, accounts for perhaps only one-sixth of all drug-related crime [51]. Hence, depending on the elasticity of demand, driving up prices could actually increase, not decrease, drug-related crime [53].

Hence, once the market has matured, it may be more constructive to task enforcement with controlling market-related externalities (notably crime and disorder) rather than seeking to reduce use by suppressing supply across the board [54].

To summarize, it is difficult to evaluate the effectiveness of supply control interventions. Randomized controlled trials are not possible, and even good natural experiments are rare. However, it is possible to build policy simulation models of the production and distribution networks and how they respond to drug control interventions. These models are indispensable for structuring the thinking about potential effects of supply control programs and for generating insights about the relative cost-effectiveness of at least a subset of them.

MODELING SHOCKS TO THE DISTRIBUTION SYSTEM

There has been growing interest in modeling how operations should respond to unusually stressful circumstances, ranging from humanitarian logistics responding to a war or physical disaster [55] to airlines trying to recover from severe weather [56]. (See also the section titled “Humanitarian and Public Service Applications” in this encyclopedia.)

Drug policy explores the inverse problem. Instead of asking how activities can be designed to remain robust in the face of disruptions, the goal is to understand how disruptions can be designed to interfere with

normal operations. One line of work focuses on disrupting local street markets, using differential equation models [57–62] and more recently, agent-based methods [63–65]. Another focuses on disrupting international distribution networks by drawing on models used in military logistics [66–68] and creating custom models [69,70]. A related line of research asks how to exploit a disruption once one has been created [71,72].

The potential for disruptions is clear. At one time or another, there have been major disruptions of the markets for every major illegal drug. A conspicuous recent example is the so-called Australian heroin “drought” [73]. Market disruptions appear to correlate with contemporaneous changes in measures of price, purity, drug test results (for arrestees and the workforce more generally), treatment admissions, and overdose [46,74–79].

Figure 3 illustrates such a correlation with data from the Australian state of Victoria, which experienced a severe disruption to its heroin market in early 2001. As the left panel of Fig. 3 shows, prices per “raw” gram did not change much because of the standardized pricing, but purity plummeted, so price per pure gram spiked sharply. The right panel shows both the trend in ambulance calls for

Figure 3. (a) Trends in the price per pure gram of heroin in Victoria, Australia; (b) graph of price series raised to a constant elasticity can explain most of the variation in ambulance calls for heroin overdose.

heroin overdose and the numbers that would be predicted by feeding the purity-adjusted price series into a standard constant elasticity demand model. The predicted and the actual series are very highly correlated. That is, simply raising the price per pure gram to a power (called the *elasticity*) and scaling it by a multiplicative constant creates a series that strongly parallels the actual trends in overdose.

There remains enormous debate about what exactly caused the Australian heroin drought [78]. Perhaps the most plausible explanation is that Australian Federal Police were able to dismantle the small number of organizations capable of importing shipments of more than 100 kg at a time [79]. Figuring out exactly what caused past market disruptions and how to reproduce them in the future is an important area of research to which OR/MS has much to contribute.

OPTIMAL DYNAMIC CONTROL MODELS

Drug use varies over time in a manner that is referred to as an *epidemic cycle*. From initially low levels before markets have fully developed, drug initiation and use grow rapidly, as described in Fig. 1. After a time, initiation peaks and shortly thereafter, overall prevalence and light use do too. While total prevalence falls, the number of heavy users can still grow because escalation to heavy use occurs with a lag. At this point, the epidemic switches into an endemic stage, characterized by an aging pool of dependent users that is partially but not completely replaced by an ongoing lower level of initiation and light drug use.

The initial “systems models” [27] estimated the relative cost-effectiveness of different drug control interventions under the implicit assumption that the drug problem had stabilized in this endemic stage. However, there is no reason to believe that the mix of drug control strategies that is optimal at one stage of a drug epidemic is the best for other stages. That is, it is possible that drug policy should evolve as the drug problem does.

Building on earlier research on dynamic law enforcement [80,81], researchers from

the Vienna University of Technology used optimal dynamic control theory to investigate the possibility of different control strategies being effective at different states of a drug epidemic. These models offer a number of policy recommendations. For example, law enforcement is relatively most effective early in an epidemic, when the market is still small. Hence, when policy makers become aware of a burgeoning problem, it may be advisable to make a discrete choice between an “eradication” strategy that seeks to drive the problem down to a low level equilibrium and an “accommodation” strategy that only seeks to slow its growth to a high level equilibrium, using a mix of control spending that shifts more and more over time toward treatment [82]. Zeiler [20] extends the accommodation strategy results by showing that there can also be choices between a relatively passive accommodation and a grudging accommodation that fights a holding strategy as long as possible.

Behrens *et al.* [15,16] explore timing issues for treatment and prevention. Perhaps not surprisingly, the model suggests allocating a substantially larger share of a drug control budget to prevention early in an epidemic and treatment later. (Winkler *et al.* [17] go on to distinguish a number of varieties of prevention.) Wallner [21] suggests that later in an epidemic, harm reduction interventions can be useful, even if earlier they might have risked “tipping” an epidemic to a higher level of use by promoting initiation. (Harm reduction interventions that have no adverse effect on drug prevalence could be useful at any point in an epidemic.)

Most of this optimal dynamic control work has modeled just one drug at a time, but Zeiler [20] explores multiple-interacting drug epidemics within an optimal control framework. This natural extension is akin to what Margaret Brandeau, Elisa Long, Gregory Zaric, and others have done for allocating resources across competing epidemics of HIV in different populations [20,83,84].

To summarize, people have long recognized that no one policy is best for all drugs and places, but this section observes that similarly no one policy is best for all times (epidemic stages) even for a given drug and

location. Policy makers readily accede to this idea that since drug use evolves over time, drug policy should too. However, the standard analytical tools of most of the disciplines that study drug policy are not designed to frame policy analysis in this way. In contrast, OR/MS has tools that can grapple with problems in terms of dynamic optimization, specifically optimal dynamic control theory.

RELATED TOPICS AND OPPORTUNITIES FOR FURTHER RESEARCH

Drug policy is a complicated domain. From a mathematical perspective, the system is characterized by nonlinear endogenous feedback, inertia, lags, market equilibria, disequilibrium adjustments, multiple objectives, multiple stakeholders, and great uncertainty. This complexity can overwhelm humans' intuitive reasoning, and unintended consequences are rampant even for well-intentioned interventions. Fortunately, many pieces of this complex system parallel phenomena that OR/MS has studied for decades. Hence, OR/MS tools can be enormously helpful in bringing precision and clarity to thinking about drug policy.

In particular, drug initiation, $I(\mathbf{X}, \mathbf{u})$, behaves like new product adoption. The ongoing evolution of a drug epidemic has a Markovian character, $d\mathbf{X}/dt = g(\mathbf{X}, \mathbf{u}) + I(\mathbf{X}, \mathbf{u})$. The resulting demand, $Q_D(\mathbf{X})$, intersects with supply, $Q_S(\mathbf{X}, \mathbf{u})$ and any supply shock, $\varepsilon(\mathbf{u})$, to determine a market clearing price, p , that satisfies

$$Q_D(\mathbf{X}; p) = Q_S(\mathbf{X}, \mathbf{u}; p) + \varepsilon(\mathbf{u}).$$

The equilibrium is dynamic, not static, so the overall policy problem can be thought of as finding a policy vector $\mathbf{u}$ that evolves over time in a way that minimizes the integral of the costs of drug use ($c_1(\mathbf{X}, p)$) and control ($c_2(\mathbf{u})$):

$$\begin{aligned} \text{Min } J &= \int_0^\infty e^{-rt} (c_1(\mathbf{X}, p) + c_2(\mathbf{u})) dt \\ \text{s.t. } d\mathbf{X}/dt &= g(\mathbf{X}, \mathbf{u}; p) + I(\mathbf{X}, \mathbf{u}; p) \text{ and} \\ Q_D(\mathbf{X}; p) &= Q_S(\mathbf{X}, \mathbf{u}; p) + \varepsilon(\mathbf{u}). \end{aligned}$$

Many insights stem just from analyzing the various pieces in isolation, but the dynamic optimization formulation provides a concise framework for understanding how the various pieces interact.

This review of OR/MS applied to drug policy has been selective, describing a few ideas in enough detail to appreciate their contributions rather than giving a brief paragraph about each. We have omitted much, notably a companion stream of research on the intersection of injection drug use and HIV and HCV pioneered by Kaplan's "Needles that Kill" [85,86] model and subsequent work quantifying drug treatment's cost-effectiveness when factoring direct and secondary reductions in disease transmission [87–92].

Similarly, there are exciting developments in network and agent-based models of drug markets and drug enforcement that merit their own review [93–98].

It is important to note, though, that even a comprehensive review of drug policy systems modeling would leave the majority of the drug policy questions unanswered. The corpus of research to date merely scratches the surface of what could be done.

Economists frequently talk about "diminishing returns" whereby the incremental benefit of additional units of a resource decreases the more of that resource that has been allocated. Such a principle may apply with respect to analysis of drug policy problems. While some disciplines that have studied drug policy for decades may have reached diminishing returns, there are still relatively few people with an engineering mind set who study drug control problems, so much low-hanging fruit remains to be harvested.

FOUNDATIONS AND MOTIVATION

This article regards optimization problems of the form

$$\text{minimize } f(\mathbf{x}), \text{ subject to } \mathbf{x} \in X, \quad (1)$$

where f is a (multivariate) objective function, $\mathbf{x}$ represents the solution vector, and X represents the problem's set of feasible solutions. For the sake of simplicity in this article, we assume that X is nonempty and that problem (1) has an optimal solution.

When problem (1) has certain special structures, specialized algorithms can be used to quickly obtain optimal solutions to the problem. However, especially when X contains *discreteness* restrictions on $\mathbf{x}$ (e.g., elements of $\mathbf{x}$ must be binary-valued, or represent a permutation of a set of integers), f is a nonconvex function, and/or X is not representable by (a reasonable number of) convex constraints, problem (1) may be quite difficult to solve to optimality. In fact, some of these problems are known to be *NP-hard*, and thus no algorithms that can solve these problems in polynomial time are believed to exist. (Informally, a polynomial-time algorithm is guaranteed to solve a problem in time proportional to a polynomial function of the “size” of the problem, usually given as the maximum of the number of problem elements and the number of binary bits

required to store the problem's data. See Papadimitriou [1] for more information on computational complexity, and the seminal work of Garey and Johnson [2] for the theory of NP-completeness.)

Many real-world optimization problems are indeed NP-hard, and reasonably sized instances are thus difficult or impossible to solve to optimality within reasonable computational limits. A common strategy is to relax one's insistence on obtaining an optimal solution to the problem, and instead concentrate on finding a solution that appears to be near-optimal. Hence, much research has been performed on the use of polynomial-time heuristic algorithms for solving difficult optimization problems. In particular, *metaheuristic* approaches describe general frameworks for heuristic methods that can be adapted to suit a wide array of diverse optimization problems. The topic of this article is one such metaheuristic technique called *tabu search*.

Tabu search first specifies an initial starting point for the search procedure, and then iteratively moves the current solution to a *neighboring solution* (one that is obtainable as a small perturbation from the current solution, as we will discuss in the next section). One particular search strategy, called *local search*, simply moves to a neighboring solution having the best-objective function value, until the current solution's objective function value is at least as good as all of its neighboring solutions' objective function values. This is also called *greedy search*. In this case, we say that the current solution is *locally optimal*, in the sense that it is optimal among solutions in its neighborhood. However, local optimal solutions may have objective function values that are far inferior to that of a *global optimal solution* (i.e., a solution $\mathbf{x}^*$ that optimizes problem (1)). The primary goal of tabu search is to avoid being stuck in local optima, while at the same time avoid getting stuck in a loop. We discuss the tabu search metaheuristic in the section titled “Tabu Search,” along with several issues that

arise when tailoring tabu search implementations on specific problems. We then briefly discuss a sample of applications on which tabu search has been effectively used in the section titled “Applications of Tabu Search.”

TABU SEARCH

We present the basic tabu search metaheuristic in the section titled “Basic Tabu Search Framework” and comment on its enhancements in the section titled “Extensions and Improvements.” We also refer the reader to excellent classical discussions of tabu search by Fred Glover [3–5], the manuscript by Glover and Laguna [6], and a tutorial treatment of the material by Gendreau [7]. To aid us in illustrating this technique, we consider the following two optimization problems.

Traveling Salesman Problem (TSP). Consider a set $V = \{1, \dots, n\}$ of nodes, with a distance measure of d_{ij} from node $i \in V$ to node $j \in V$. The TSP seeks a minimum-cost simple cycle (or tour) that starts and ends at node 1, and visits every node in V exactly once. We say that arc (i, j) is taken in the TSP tour if we travel directly from node i to node j in the tour. Letting P be the set of all arcs in a tour, the total cost of a tour is given by $\sum_{(i,j) \in P} d_{ij}$.

Parallel Job Scheduling Problem (PJSP). Consider a set $J = \{1, \dots, n\}$ of jobs that are processed on a set $M = \{1, \dots, m\}$ of machines, where job $j \in J$ takes p_{jk} hours to complete on machine $k \in M$ and only one job may be performed on a machine at a time. There are several possible objectives here; we will consider one of minimizing total completion time. The completion time of job j is simply the time at which it finishes processing, and the objective minimizes the sum of all job completion times.

Both of these problems are (strongly) NP-hard. The TSP is a classical domain of study for metaheuristic research; see Malek *et al.* [8] for an early study of serial and parallel tabu search algorithms for its

solution. Machine scheduling has also been a major focus of metaheuristic research in general; see Hübner and Glover [9] for an application of tabu search to multiprocessor scheduling.

Basic Tabu Search Framework

For our initial discussion, let us assume that finding feasible solutions to X is straightforward. tabu search begins by specifying an initial solution $\mathbf{x} \in X$ and characterizing a set of neighboring solutions $N(\mathbf{x}) \subseteq X$. Indeed, this step requires two of the most important decisions in designing a tabu search algorithm: (i) how to represent the decision variables $\mathbf{x}$ (i.e., the encoding of the solution), and (ii) how to construct the neighborhood $N(\mathbf{x})$. These two decisions are interrelated, and are typically the most important factors in determining how well the algorithm will perform.

Solution Encoding. In the context of the TSP and PJSP, note that either problem may be formulated as a mixed-integer programming (MIP) problem, and $\mathbf{x}$ could simply refer to the binary variables required in these formulations. For the problems at hand, however, there are more effective ways of problem representation, and we exploit the special constraint structure of the problems under investigation to devise a compact encoding for which neighboring solutions can easily be devised.

For instance, in the TSP, we use a *permutation encoding* on the integers $1, \dots, n$, that is, a sequence of integers such that every integer $1, \dots, n$ appears exactly once (in some order). We let x_j (the j th integer in a permutation solution $\mathbf{x}$) be the j th node visited in a TSP tour, where $x_1 = 1$ is fixed to indicate that the tour (arbitrarily) starts and ends at node 1. The last leg of the tour is then from the last node in this permutation back to node 1. It is easily seen that every permutation vector, starting with 1, represents a feasible solution. The computational problem is that there are $(n-1)!$ different permutations. More thought is perhaps needed for PJSP. In this case, it is possible to specify for each job the machine on which it is placed as well as the order in

which it is scheduled on the machine (e.g., x_j could refer to a pair $(k, \pi(k))$, where k represents the machine on which j is scheduled, and $\pi(k)$ represents the order in which the job is scheduled). However, this scheme would require the algorithm to ensure that a permutation sequence is enforced on each machine (e.g., two jobs cannot be processed first on the same machine). A well-known result in scheduling theory asserts that, given a minimum completion time objective and a set of jobs to be assigned to a single machine, an optimal schedule places jobs on the machine in nondecreasing order of their processing time. Hence, a more elegant (and effective) scheme is to simply let x_j represent the machine on which job j is scheduled. Given this information, a postprocessing step can then be performed to schedule the jobs on each machine (by sorting) and determine the objective function value of a candidate solution. This discussion in fact underscores the importance of exploring characteristics of a problem under study and using such knowledge within a tabu search (or indeed, any metaheuristic) algorithm, as emphasized in Gendreau [7].

Neighborhood. Given a solution encoding, the neighborhood of the solution $\mathbf{x}$ is determined by identifying an operation, or a set of operations, that slightly perturbs $\mathbf{x}$ while retaining feasibility to the overall problem. For instance, consider a solution $\hat{\mathbf{x}} = (1, 2, 5, 4, 3, 7, 6)$ to a seven-node TSP instance. Simply letting $N(\mathbf{x})$ be the set of all vectors that change only one element of $\mathbf{x}$ would result in infeasible solutions, as it would ruin the permutation property of $\mathbf{x}$. In the above example, if we change $\hat{x}_7$ to equal 7, then node 7 would be visited twice, and node 6 skipped. Instead, we could let $N(\mathbf{x})$ be a 2-opt neighborhood (which is very commonly used in permutation encodings) in which $\tilde{\mathbf{x}} \in N(\mathbf{x})$ if and only if swapping some pair of element values x_i and x_j in $\tilde{\mathbf{x}}$ yields $\mathbf{x}$. For instance, solution $\mathbf{x}^1 = (1, 2, 7, 4, 3, 5, 6)$ would be a 2-opt neighbor of $\hat{\mathbf{x}}$ in the above example.

However, once again we see that it is vital to employ knowledge of the problem under investigation. Note that $\mathbf{x}^1$ differs from $\hat{\mathbf{x}}$ by

four arcs: $\mathbf{x}^1$ uses arcs (2,7), (7,4), (3,5), and (5,6), replacing the arcs (2,5), (5,4), (3,7), and (7,6) in $\hat{\mathbf{x}}$. If the TSP is *symmetric*, where $d_{ij} = d_{ji}$ for all $i, j \in V$, then an alternative neighborhood picks two nodes to swap, but then reverses the entire subsequence in between those two nodes. Using the above example, this would yield $\mathbf{x}^2 = (1, 2, 7, 3, 4, 5, 6)$. Note that the perturbation between $\hat{\mathbf{x}}$ and $\mathbf{x}^2$ is now only two arcs: $\mathbf{x}^2$ uses arcs (2,7) and (5,6) in place of arcs (2,5) and (7,6) in $\hat{\mathbf{x}}$ (although some other arcs are traversed in the opposite direction as before). Hence, this 2-opt-reverse neighborhood, while being of the same size as a standard 2-opt neighborhood, contains solutions that are smaller perturbations of the original solution.

In general, the best results typically come from designing an encoding/neighborhood pair such that neighboring solutions $\tilde{\mathbf{x}} \in N(\mathbf{x})$ are very similar to $\mathbf{x}$, which motivates the 2-opt-reverse strategy for TSP. Note that in PJSP (unlike TSP), it is valid to let $N(\mathbf{x})$ be a set of 1-opt switches to $\mathbf{x}$, in which a single element of $\mathbf{x}$ changes its value from one machine assignment to another. However, the number of solutions in $N(\mathbf{x})$ should ideally be large enough to permit the search strategy to explore X as broadly as possible, while still limiting the overall complexity of the algorithm. Thus, it may also prove beneficial to include those vectors that are obtainable from 2-opt changes as well, in order to more broadly search X . At the same time it is of high importance to keep the size of the neighborhood limited, to ease the computational burden.

Tabu Tenure and Aspiration Criteria. Recall that local search chooses a starting point $\hat{\mathbf{x}} \in X$, moves to a best-objective neighbor in $\tilde{\mathbf{x}} \in N(\hat{\mathbf{x}})$, sets $\hat{\mathbf{x}} = \tilde{\mathbf{x}}$, and repeats until no solution in $N(\hat{\mathbf{x}})$ is strictly preferable to $\hat{\mathbf{x}}$, that is, until $\hat{\mathbf{x}}$ is a local optimum. In this sense, local search gets “stuck” at a local optimum (depending on the starting point). Tabu search avoids getting stuck in local optima by maintaining a limited memory of selected attributes of its last ℓ moves (where ℓ is a positive integer that is determined by the metaheuristic developer), and by restricting moves to neighboring solutions that contain

these attributes. Such moves are said to be tabu (or forbidden), and the limited memory used to store the selected move attributes is called the *tabu list*. The number of iterations that this information is stored for a given move is called the *tabu tenure*.

Determining how to select these attributes is an important consideration in designing tabu search algorithms. In the TSP example, it may be appropriate to remember the node indices that are swapped (e.g., nodes 5 and 7), and mark as tabu any move that swaps these nodes. An alternative would be to mark as tabu all moves containing node 5 or node 7. Alternative attributes of the move might be the set of new edges included by the move, or the set of old edges excluded (and/or both sets). For one-swap PJSP neighborhoods, we may record the job being switched and the machine from which it was switched. A separate tabu list may be stored for 2-opt changes as well, which could be implemented as multiple tabu lists, one for each type of neighborhood perturbation (see e.g. the discussion in Chapter 2 of Talbi [10] on maximum independent set problems).

An important distinction must be made between tabu search and local search at this point. Tabu search algorithms continue to move to a neighbor having the best-objective function value, provided the corresponding move attributes are not on the tabu list, *even if this best-objective neighbor has an objective that is inferior to that of the current solution*. This feature allows tabu search to move the solution away from local optima where the objective function of the current solution can deteriorate.

In a simplistic tabu search implementation, all solutions reached by tabu moves would be forbidden (although we relax this assumption in our subsequent discussion of aspiration criteria). It is easy to see that soon, if the tabu tenure were long enough, all moves would become tabu. Therefore, we retain only the selected attributes of the ℓ moves in the tabu memory. If ℓ is too small, then the metaheuristic cycles more easily: The current solution will move away from a local optimum, but fall back toward this local optimum as the tabu status of the moves it has taken to escape the local optimum ends

too quickly. If ℓ is too large, then most of the reachable neighborhood is tabu, and the search is highly restricted. One tends to tune a tabu search algorithm to find an appropriate balance between these two concerns. It is also customary to assign a tabu tenure that is randomized inside an interval (e.g., between 10 and 15) every time some move attribute is given a new tabu tenure. This helps to avoid being stuck in longer loops, and also diversifies the search.

Still, one common device used in these algorithms is that of *aspiration criteria*. The tabu criteria might sometimes be overly restrictive, in that otherwise good moves would be classified as tabu. The purpose of an aspiration criterion is to identify such moves and temporarily override the tabu status. Typically, the simplest and most effective rule is to determine whether a tabu move leads to a solution that has a new best-objective function value. (Other aspiration criteria might be devised, and the reader is encouraged to consult Glover [6] for further details.)

Overall Procedure. Having specified a solution encoding and neighborhood set, the tabu attributes and associated tabu tenure, and the aspiration criteria, we can now state the overall tabu search procedure as follows:

- Step 1.* Choose an initial solution $\hat{\mathbf{x}} \in X$. Let the incumbent solution $\mathbf{x}^* = \hat{\mathbf{x}}$ with objective function value $f^* = f(\hat{\mathbf{x}})$. Set the iteration counter $t = 0$.
- Step 2.* If $t == \text{MAXNUM}$ (where MAXNUM is a prespecified maximum number of tabu search iterations), then terminate with solution $\mathbf{x}^*$. Otherwise, continue to Step 3.
- Step 3.* Compute $f(\mathbf{x}) - f(\hat{\mathbf{x}})$ for every $\mathbf{x} \in N(\hat{\mathbf{x}})$, typically by evaluating the objective function change due to moving from $\hat{\mathbf{x}}$ to $\mathbf{x}$, and set $S = N(\hat{\mathbf{x}})$. Continue to Step 4.
- Step 4.* Let $\tilde{\mathbf{x}}$ be a solution that minimizes $f(\tilde{\mathbf{x}}) - f(\mathbf{x})$ over $\mathbf{x} \in S$. If the move from $\hat{\mathbf{x}}$ to $\tilde{\mathbf{x}}$ is tabu and does not meet the aspiration criteria, then delete $\tilde{\mathbf{x}}$ from S and repeat Step 4. Otherwise, continue to Step 5.

Step 5. Set $\hat{\mathbf{x}} = \tilde{\mathbf{x}}$. If $f(\hat{\mathbf{x}}) < f^*$, then $\hat{\mathbf{x}}$ becomes the new incumbent solution: Set $\mathbf{x}^* = \hat{\mathbf{x}}$ and $f^* = f(\hat{\mathbf{x}})$. The tabu memory is updated with the attributes and selected tabu tenure for the current move. In either case, increment t by one and return to Step 2.

Note that in Step 5, we remember the best solution found so far in the algorithm, and in Step 2, we report the incumbent solution as the final answer, rather than the last answer obtained. This is because the objectives encountered by tabu search are nonmonotonic, and hence it is quite possible that tabu search encounters its best solution early in the search.

As for termination criteria, we specify a very basic limit on the total number of iterations (solution moves) made throughout the algorithm. Several other criteria are possible, such as the maximum number of moves made without finding a new best solution in Step 5, or a time limit.

Extensions and Improvements

As this article is an introductory-level treatment of tabu search, we have only presented the foundational concepts behind the metaheuristic, leaving the more advanced notions for future reading. Here, we briefly discuss several considerations in implementing effective tabu search algorithms. More advanced treatments of this area can be found in Gendreau [11], Glover and Laguna [6], and Talbi [10].

Computational Techniques. In Step 3 of the metaheuristic description given above, we compute the change in the objective function value, $f(\mathbf{x}) - f(\hat{\mathbf{x}})$ (as opposed to recomputing $f(\mathbf{x})$ from scratch) based on the knowledge of the problem structure, in order to reduce computational effort. For instance, using a 2-opt-reverse neighborhood for a symmetric TSP, suppose that we know the objective function value $f(\hat{\mathbf{x}})$ for a current solution $\hat{\mathbf{x}}$. We can compute the objective function value of a neighboring solution by subtracting the costs of the two broken arcs in $\mathbf{x}$,

and adding the costs of the two new arcs in the neighboring solution. Each new objective function computation thus requires only four floating-point operations (or eight in an asymmetric TSP with 2-opt neighborhoods), rather than the n operations that would be required if $f(\tilde{\mathbf{x}})$ were computed from scratch for each $\tilde{\mathbf{x}} \in N(\hat{\mathbf{x}})$. (In fact, the effort here can be further reduced by exploring the neighborhood in a special order.)

Another computational consideration may arise if the number of solutions in the neighborhood is prohibitively large. In this case, it may be advantageous to explore only a subset of the neighboring solution space rather than enumerating the entire neighborhood. The proportion of neighborhood solutions evaluated can be dynamically changed throughout the algorithm, depending on the quality of solutions identified.

General Constraints. The TSP and PJSP discussed above have special constraint structures that allow solutions to be easily encoded, with their feasibility guaranteed. These structures are not necessarily present in all applications, though. Rather than explicitly enforcing the feasibility of candidate solutions to satisfy these constraints, we can instead penalize the degree to which constraints are violated. If the penalties are large, then infeasible solutions are essentially prohibited by the algorithm, which can unduly restrict the extent of the search space explored. It may be more preferable to adjust the penalties for infeasibility, starting with moderate values for the penalty and increasing them gradually during the course of the algorithm (as recommended in Gendreau [7]).

Intensification. The practice of intensification is based on the intuition that, even if tabu search fails to identify an optimal solution, it may have identified several solutions that are near an optimal solution. By keeping memory of, say, the β best unique solutions encountered, it may be appropriate to return to these solutions after the tabu search algorithm has finished executing, and explore them more intensely.

Several other intensification strategies, most depending on the problem under investigation, are also presented in the literature. Gendreau [11] prescribes fixing certain aspects of these candidate solutions (e.g., arcs that frequently recur in near-optimal TSP solutions, or machine assignments for promising PJSP solutions), and Hertz *et al.* [12] recommend partitioning and limited enumeration methods using these candidate solutions as starting points.

Diversification. The aim of diversification is to induce the search process to escape the currently explored part of the search region and explore other areas that may look promising. This feature of tabu search essentially employs a “long-term memory” by retaining information about previously visited solutions. This memory is often frequency based, as opposed to the recency-based tabu memory discussed above.

The simplest diversification strategy is to randomly restart the algorithm presented in the section titled “Basic Tabu Search Framework” by choosing different starting points $\hat{x} \in X$ in Step 1. Hence, the tabu search algorithm would essentially be run over several trials, retaining the best incumbent solution found over all of the trials. One may bias the selection of these initial solutions by encouraging them to be different in some way from prior starting solutions, and also from best solutions identified from the previous trials. In the generation of TSP tours, one might randomly generate a starting tour that attempts to avoid the inclusion of links that have appeared in these prior solutions. A PJSP diversification scheme may simply avoid assigning some jobs to machines on which they have commonly been assigned in previous solutions. Furthermore, for a case in which the search space X can be effectively partitioned into multiple sets $X_1, \dots, X_q$ (all of which are disjoint, with $X_1 \cup \dots \cup X_q = X$), Laguna *et al.* [13] prescribe a strategy in which starting solutions are generated roughly equally from among the q different sectors.

Soriano and Gendreau [14] call this method *restart diversification*, and draw a distinction between it and *continuous*

diversification, in which the objective of diversification is pursued during the evaluation of moves. Continuous diversification also attempts to avoid repeating portions of previous solutions that have been identified (e.g., links commonly appearing in a TSP solution or job-to-machine assignments occurring in a PSJP solution). However, it does so by penalizing these repeated portions within the ongoing evaluations of moves in the evaluated neighborhood. Hence, moves leading to solutions exhibiting substantial similarities to previously visited solutions are penalized, and the search process thus moves toward less frequently visited areas of the search space.

APPLICATIONS OF TABU SEARCH

Since tabu search is extremely effective in providing high-quality (and frequently optimal) solutions to complex problems, it has seen extensive application in a wide variety of problems since its creation by Glover [3–5] in the late 1980s. Our objective in this section is to foster in the reader an appreciation of the breadth of tabu search application, and not to discuss all published accounts of tabu search applications, so we focus on applications that have been published in the past few years.

Tabu search is frequently applied to complex scheduling problems. Korsvik *et al.* [15] and Korsvik and Fagerholt [16] use tabu search to increase revenues of shipping companies that transport bulk products by using space that is not contractually committed to ship spot cargoes. Hu *et al.* [17] also study shipyard operations, but focus on scheduling of a pipe-processing flowshop that comprises five stages (cutting, bending, welding preprocessing, argon-welding, and CO₂-welding), where each stage consists of identical parallel machines.

The vehicle routing problem (VRP) is a notoriously difficult combinatorial optimization problem that seeks a set of tours in a network that collectively service a set of nodes, for example, by picking up (or dropping off) items located at these nodes. Capacitated versions of the VRP include data regarding

the size of items to be picked up at each node and vehicle capacities that limit the total size of items that a vehicle can pick up. Gendreau *et al.* [18] devise one of the first tabu search approaches to solving the VRP with vehicle capacity and route length restrictions. In their implementation, neighboring solutions are created by swapping a single vertex from its current route to a new route. Oppen and Løkketangen [19] employ tabu search for solving a livestock collection problem, in which vehicle loading is subject not only to capacity limits, but also to restrictions on combinations of animals that can be loaded onto the same vehicle. The authors also consider a number of other real-world considerations in their model and demonstrate that their solutions are significantly superior to those currently in use. Zachariadis *et al.* [20] consider the case in which items are associated with two-dimensional sizes, and these items must be packed onto a vehicle's loading surface. Hence, the problem not only partitions the nodes into routes that are serviced by vehicles but also specifies the manner in which items are packed onto the vehicles. Cordeau *et al.* [21] provide a simple and effective tabu search algorithm for the VRP, in which each node is associated with a time window during which it can be visited by a vehicle. See also the two-part survey in Bräysy and Gendreau [22,23] for a more recent catalog of local search and meta-heuristic algorithms for the VRP with time windows.

Finance and capital investing are other related areas that are rife with applications of tabu search. A prime example is the work of Aldaihani and Al-Deehani [24], who focus their efforts on balancing risk and return when building a portfolio of investments available through the Kuwait stock exchange. One of their models aims to maximize expected return while maintaining a desired maximum level of risk, and their other model minimizes portfolio correlation while maintaining expected return at or above an acceptable minimum level. A mean-risk multistage capacity investment problem with irreversibility, lumpiness, and economies of scale in capacity costs is considered by Claro and Sousa [25], who use

conditional value-at-risk as their risk measure. These authors also solve this problem with a hybrid approach that combines tabu search and variable neighborhood search.

Network design is yet another area in which tabu search has been frequently employed. Pedersen *et al.* [26] develop a generic model for service network design (which includes asset positioning and utilization through constraints on asset availability at terminals) and solve both arc- and cycle-based formulations for their model with tabu search. Easwaran and Üster [27] apply two tabu search heuristics (sequential and random neighborhood search procedures) to a network design problem in a multiproduct closed-loop supply chain that incorporates remanufacturing facilities and finite-capacity manufacturing, distribution, and collection facilities that serve a set of retailers. The authors' objective is to determine the locations of the collection centers, locations of the remanufacturing facilities, and the integrated forward and reverse flows that will minimize the total cost of facility location, processing, and transportation associated with forward and reverse flows in the network. Yamada *et al.* [28] use tabu search in combination with other approaches to aid in strategic transport planning (particularly in freight terminal development and inter-regional freight transport network design) through the design of multimodal freight transport networks that facilitate regional and/or national economic development while reducing negative environmental impacts. Dengiz *et al.* apply each tabu search, genetic algorithms, and simulated annealing [29] to a different type of network—a back propagation neural network—to train the network and overcome the back propagation neural network's slow convergence rate and the tendency to converge to a local optimum.

Tabu search has also been applied to health care problems in several instances. The problem of composing medical crews in a manner that maximizes the equity and efficiency of the care provided by the crews was addressed by Aringhieri [30] with tabu search. In another health care application, Hertz and Lahrichi [31] use tabu search to assign patients to nurses for home care

services in a manner that balances the workload of the nurses while avoiding long travels for patient visits. Beaudry *et al.* [32] solve the problem of providing efficient and timely transport service to patients over several locations in a hospital campus, addressing the dynamic nature of transportation requests and varying priorities of the requests in such systems. The authors use a two-phase approach in which a simple insertion scheme is used to generate a feasible solution in the first phase and tabu search is used to refine and improve this feasible solution in the second phase. Erdoğan *et al.* [33] use tabu search to schedule ambulance crews to maximize coverage over a planning horizon.

The examples described above do not convey the breadth of application of tabu search. Gelogullari and Logendran [34] address flow-shop group-scheduling problems that are typically encountered in printed circuit board assembly. These authors specifically formulate their model to account for characteristics inherent to group-scheduling problems common in both electronics manufacturing and other production environments. Samarghandi and Eshghi [35] apply tabu search to a single-row facility layout problem (SRFLP) to linearly place a given number of rectangular facilities in a manner that minimizes the total cost associated with their known or projected interactions. Berman *et al.* [36] also apply tabu search to facility location, but consider the problem of finding the p locations for p facilities that minimize the maximum load associated with any individual facility (as a means of avoiding large discrepancies in loads associated with the facilities).

A multiorder processing procedure in a just-in-time (JIT) environment is modeled as a cost-based job shop problem, and work-in-process holding cost of half-finished orders, inventory holding cost of finished orders, and backorder cost of unfulfilled orders are minimized by Zhu *et al.* [37] through a modified tabu search method. In an effort to improve the operational efficiency of seaports and develop an analytical tool for yard operation planning, Wong and Kozan [38] use tabu search to solve a model that

incorporates relationships between quay cranes, yard machines, and container storage locations in a multiberth and multiship environment. Brusco and Steinley [39] apply neighborhood search heuristics to the statistical problem of selecting promising variable subsets for polynomial regression. Hertz *et al.* [40] report encouraging results in their application of tabu search to the auto rental company inventory management problem that was the ROADEF'99 international challenge. Mukherjee and Ray [41] search for optimal path conditions for multistage and multiresponse grinding in mass-scale manufacturing; they first consider each stage to be independent, then consider all stages as a single system, and solve both models with tabu search. Bouchard *et al.* [42] propose a specialized tabu search algorithm for finding an edge coloring with a minimum deficiency for a given graph.

As we have already seen, tabu search is often used in conjunction with other algorithmic approaches. Another recent example of this strategy includes the method of Lin and Ying [43], who develop a hybrid of tabu search and simulated annealing to minimize the makespan of the nonpermutation flow-shop scheduling problem. Rao and Shyju [44] use an algorithm that combines desirable qualities of simulated annealing and tabu search to solve multiobjective combinatorial optimization problems; they evaluate their algorithm on stacking sequence optimization problems for hybrid fiber-reinforced composite plate, cylindrical shell, and pressure vessel problems.

Finally, several authors have used tabu search to solve complex problems dealing with integrated functions or systems. Caramia and Giordani [45] propose an approach to managing the modes of task assignment and scheduling in an integrated manner. They formulate the problem as a single-mode task scheduling problem, model it as a graph interval T -coloring, and solve it using a tabu search approach. Tang *et al.* [46] examine a problem that deals with coordination of scheduling production and transportation in a steelmaking shop, and consider systems in which (i) there is a converter at the steelmaking operation and

a refining furnace at the refining operation and (ii) jobs are processed in identical parallel converters and then transported from an individual converter by dedicated trolley to the next operations. The integrated machine allocation and layout problem, that is, simultaneously assigning a set of machines to locations and product flows to machines in a manner that minimizes total material handling costs, is solved using tabu search by Jaramillo and McKendall [47]. Giallombardo *et al.* [48] integrate the berth allocation problem and quay crane assignment problem for container terminals. Their objective is to maximize the total value of chosen quay crane profiles while minimizing housekeeping costs generated by transshipment flows between ships, and they solve their problem with an algorithm that combines tabu search with classical mathematical programming techniques.

INTRODUCTION

In response to increased pressure from the public at large, as well as green organizations and the NGOs, governments around the globe have started to enact directives and pass legislation to tighten the control on waste generation and to reduce environmental damages. There are several types of environmental legislation that are currently in place or being planned, which differ in terms of the product life cycle phase the legislation is mostly concerned with. For instance, the EU's Framework Directive (2005/32/EC) on the eco-design of energy using products (EuP) regulates product design, the RoHS Directive (2002/95/EC) of the EU restricts the use of certain material and substances in production, The Basel Convention directs the export of recovered (hazardous) material and disposal, and the Waste Electrical and Electronics (WEEE) Directive of EU (Directive 2003/108/EC) regulates the take-back and recovery of end-of-life products.

Among these, take-back legislation arguably has the most comprehensive impact on closed-loop supply chains (CLSCs), and therefore constitutes the focus of this article. Our objective is to provide an overview of some of these regulations that deal with the end-of-life treatment of used products and discuss their impact on CLSCs (see **Remanufacturing** for further discussion).

There are many different types of CLSCs in practice, and these structural differences impact the nature of both forward and reverse flow of products. In this article, we utilize a generic CLSC structure, where the closing of the loop occurs after the *end-of-life* phase. Specifically, we consider five phases, representing different stages of the life cycle of the product. These are the *production*, *distribution*, *use*, *collection*, and *recovery* stages. Thus, the main stakeholders in our analysis are the *producers*, *distributor/retailers*, *end user/consumers*, *collectors*, *remanufacturers*, and *recycler/processors*. We remark that we use these terms broadly. For example, the producer refers to original equipment manufacturers (OEMs) and their entire supply chains that eventually *manufacture* or *import* new products. Logistic firms are typically involved with the transportation of new products, as well as the collection of used products from end users and their transportation for recovery operations. Likewise, municipalities, local, and national governments play crucial roles in setting up the infrastructure for collection and recovery, as well as imposing regulations that impact the operations of the CLSC.

EXISTING TAKE-BACK LEGISLATION IMPLEMENTATIONS

While all existing take-back legislations have a common goal, that is, reducing the waste generated from end-of-life products, implementations significantly differ from one country to another [1,2]. Such differences naturally result in different effects on the involved stakeholders. Below we list some important factors that could have a bearing on the impact of take-back legislation on these stakeholders.

Policy Tools

An important difference between alternative take-back legislation implementations comes from the policy tools chosen. For instance,

The European Commission has chosen collection, recycling, and recovery¹ targets as a policy tool for the end-of-life management of e-waste and end-of-life vehicles (ELVs). The WEEE Directive (2003/108/EC) of the European Commission requires Member States to ensure collection of 4 kg of such waste per capita per year starting from December 31, 2006, free of charge to consumers. The new proposal, made in December 2008, calls for 65% collection rate target (by weight) to be reached by 2016. Producers are responsible for collecting and processing end-of-life products to meet regulatory targets (percentages by weight) on product recycling or recovery. These targets differ for each category of waste. For example, in the case of large household appliances the targets are 75% for recycling and 80% for recovery, whereas for small household equipment, tools, and medical devices the rates are 50% and 70%, respectively. Similarly, the ELV Directive of the European Commission (2000/53/EC) mandates free take-back of ELVs from the last owner, with target rates of 80% for reuse and recycling and 85% for recovery (to increase to 85% and 95% by 2015, respectively).

On the other hand, The State of California [3] has chosen advance recycling fees (ARFs) for the management of e-waste. The Californian legislation requires all consumers to pay a nonrefundable fee when buying a new or refurbished product that contains a cathode ray tube (CRT) monitor or an LCD screen. The fee is used by local governments to pay authorized electronic waste collectors and recyclers.

Other policy tools, such as recycling fees (per sold or per collected unit), are also used in different parts of the world, for example, in Japan or in Taiwan (see Ref. 4 for further discussion).

¹In our discussion, *reuse* means any operation by which components of used products are used for the same purpose for which they were conceived. *Recycling* means the reprocessing in a production process of the waste materials for the original purpose or for other purposes but excluding energy recovery. *Recovery* includes both recycling and energy extraction.

Financial Responsibility

Some legislation hold the producers financially responsible for the costs of take-back (*producer pays* model), while others hold the end user or the purchaser of products for the costs of product take-back (*consumer pays* model). For instance, the producers are financially and physically responsible for the treatment of e-waste according to the European WEEE Directive, while in California consumers pay an ARF at the moment of purchase to cover for take-back related costs of certain electronics products. With a slight variation, the Specified Home Appliances Recycling Law (SHARL) of Japan [2] charges end users for the costs of take-back and recycling at the moment of disposal.

Collective versus Individual Responsibility

When producers are physically responsible for the costs of product take-back, it is important to know whether the legislation enforces collective responsibility among producers or whether producers are allowed to act individually. For instance, while the WEEE Directive states that each producer should be responsible for his own waste, the majority of Member States have their producers join *collective take-back schemes* (e.g., Walloon Region of Belgium; Denmark; France; Spain; and United Kingdom). This approach has been criticized by most producers [5] because it creates fairness concerns and lacks incentives for design improvements. Accordingly, some countries (e.g., Austria, Germany, Ireland, Italy, Sweden, and The Netherlands) allow producers to form their own *individual take-back systems* (www.iprworks.org).

Recycling Markets

Some legislation require that all producers recycle the end-of-life products through a monopolistic recycler. Other types of legislation allow competition in the recycling market. While the WEEE Directive states that each producer should be responsible for his own waste, some Member States, for example, Belgium, in EU have their producers join a *single take-back scheme*. Other countries, for example, Austria, Germany,

and The Netherlands, allows producers to join one of multiple *competing take-back systems* [4]. The most important difference between monopolistic and competitive recycling market systems appears to be on the cost side. It is argued that monopolistic take-back systems create higher recycling fees and hence higher costs to the producers [6,7].

Cost Sharing

If a collective producer responsibility system is employed, the cost allocation between producers is a very important concern. Sometimes the cost allocation can be based on market shares (e.g., the current system in WEEE) or it can be based on return shares (e.g., as allowed by the legislation in Maine (www.computertakeback.com) or Japan (<http://www.env.go.jp/en/laws/>)).

IMPACT OF LEGISLATION ON CLOSED-LOOP SUPPLY CHAIN STAKEHOLDERS

In this section, we provide a detailed account of how take-back regulations influence different stakeholders in CLSCs. Our discussion here is based on our understanding of the differences between previously discussed take-back legislation.

Consumers

Consumers represent one of the most crucial stakeholders in CLSCs. Take-back legislation imposes direct or indirect financial costs on consumers. In the context of ELVs, even in countries where free take-back is implemented, consumers are still required to bring their ELVs for dismantling. In some cases, the vehicles are not in a condition to be driven, imposing additional costs to the consumers, beyond the administrative and handling fees that may be charged.² Likewise, in the context of WEEE legislation that adopts consumer pays models, the consumers are charged fixed recycling fees

at the moment of purchase (e.g., California) or disposal (e.g., Japan). Even in implementations where take-back is free to consumers (e.g., in most of EU), the costs of collection and recovery are picked up by the producers, and it is not known as to what extent such costs are reflected on the consumers. Consequently, the most direct impact of take-back legislation on the consumers is economic in nature. Consumers are directly or indirectly paying for product take-back, meaning that the consumer surplus (CS) is likely to be lower with such legislation. An immediate impact of reduced surplus is reduced future consumption [6,8].

What is the benefit from such legislation to the consumers? The answer is probably the reduction in the environmental impact from production and disposal of hazardous goods and increased environmental sustainability due to greener designs. It is therefore no surprise that many consumer organizations and NGOs have been actively involved in the establishment of take-back legislation. Consequently, the trade-off that the consumers face is between short-term economic drawbacks and long-term environmental benefits. We remark, however, that the long-term environmental benefits are likely to result in economic benefits as well. This is because without take-back legislation, consumers will have to pay for increased taxes for toxic cleanups, water stream contamination, and increased landfill space. Take-back legislation is likely to please the consumers as long as consumers are aware of such potential future costs and they care sufficiently about the environment. Otherwise, the main impact of such legislation seems to be a reduction of the CS.

Distributors/Retailers

Distributors or retailers of new products (henceforth referred to as retailers for brevity) are ideal collection points for products to be recycled within the scope of take-back legislation. This is particularly relevant for WEEE products that are relatively less bulky, enabling collection and sorting at point of sale locations. As the closest contact point to end users, retailers can be instrumental in collecting fees under

²This extra cost and hassle is one of the main reasons for garaging or roadside abandonment of ELVs.

consumer pays models. Currently in Japan, end-of-use electronics products and the associated recycling fees are collected via retailers [4]. In California, even though retailers are not involved in the collection process, they contribute to the recycling system by collecting the ARFs [3]. In the context of ELVs, retailers' contribution is relatively insignificant, serving only as drop-off points in some cases (e.g., Belgium and Italy) [9].

From the retailer's perspective, take-back legislation may have both positive and negative impact. The negative impact stems from a possible demand reduction through an effective increase in the cost to the consumers. This follows our discussion of possible reduction in CS. In addition, additional physical and administrative costs might be incurred when retailers act as designated collection points. Some of these costs are offset by allowances made for the retailers to keep a portion of the collected recycling fees in *consumer pays* systems. Such allowances are present both in California and Japan WEEE legislation. On the less tangible but positive side, these activities can be seen as a value-adding service by the consumers. Another potential benefit to the retailers is bringing the consumers back to the retail stores. Especially, with small equipment that is easy to hand in at the retailers, consumers may end up in the retail stores which may trigger potential sales of other equipment. While there is no clear indication as to how frequently this occurs, it definitely deserves more investigation.

When the retailers do not act as designated collection points, their involvement with take-back operations is relatively limited. Hence, it is less clear what positive impact such legislation has. This is particularly relevant for *producer pays* systems with collective schemes, where collection is usually taken care of by third parties.

Collectors and Logistics Service Providers

As most take-back legislation come with target collection rates and encourage easy access of the collection facilities to end users, there is more business volume created for third party collectors. These are the independent dismantling and treatment firms

dealing with ELVs, municipalities, or public points that collect WEEE (financed by local authorities and/or producers). In the case of ELV, some countries have stricter requirements for the accessibility of the collection network, which has led to the installation of many new facilities. For example, the UK ELV regulation dictates that 75% of end users should be within 10 miles on average of the nearest facility, and no one should be more than 30 miles distance [10].

Another key player in the collection phase is third party logistics providers who carry out most of the transportation activities. Product take-back legislation is likely to create more business for them as well. Here, a distinction has to be made with respect to the nature of product that is collected. When products are collected with the purpose of recycling, there are usually certain aggregation centers from which the logistics providers access the material and transfer them to the recycling facilities. This is different from collection with the purpose of reusing products or components, where additional sorting and inspection is needed to make sure that valueless junk material is not transported.

An important factor in logistics business is economies of scale. When there is a single clearing house, a collective scheme for take-back, or when the producers form consortia to handle product take-back, greater economies of scale are likely to be observed. This may result in greater benefits for the logistics providers.

Existence of second-hand markets and restrictions put on the export of waste are likely to have a significant impact on the logistics companies that take part in CLSC operations. There is an active second-hand international market for used vehicles as well as components. Likewise, many electrical and electronic types of equipment, after being reconditioned, can be sent to developing countries where there is a market for them (see, for example, www.takebackmytv.com). With take-back legislation that restricts the use and cross-boundary transport of certain material, along with international regulations like the Basel Convention, it may not be allowed to export used products

out of the country, which limits the logistics business.³ This is likely to turn the global CLSC business into a local recycling business, in turn resulting in local logistics with lower margins instead of global logistics.

Producers

It is evident that producer responsibility measures embedded in take-back legislation ensure that producers face the most direct and significant consequences. For ELVs, producers bear most or all of the costs associated with take-back and recovery. Similarly WEEE legislation with producer pays implementation imposes the direct cost on the producers. In addition, mandatory (high) targets for recovery such as those in the EU have forced firms to go beyond the recycling of valuable material, which was for the most part economically viable, and recycle additional material and combust certain waste for heat recovery. This has further increased the costs of recovery and disposal [9]. Given the intensity of competition in global markets and low profit margins, take-back legislation imposes significant economic burden on producers, and may reduce overall profitability. Consequently, the efficiency of such legislation is extremely critical for the welfare of these sectors. For instance, in some EU countries (e.g., Belgium, see www.recupel.be) where a monopolistic, collective WEEE take-back scheme is employed, producers have been quite vocal about the high recovery fees they are charged and the fact that they cannot opt out of such systems. As a result, intensive lobbying has been observed for competitive take-back systems (see www.iprworks.org). A group of major electronics producers (Braun, Electrolux, HP, and Sony) has joined forces and established the European Recycling Platform (www.erp-recycling.org) in 2002 for this purpose, and by initiating competition between schemes, they have been able to reduce recycling costs significantly in countries such as Austria, Germany, and Ireland.

³We remark that despite these regulations, significant amount of WEEE and ELVs end up (illegally) in developing countries [2].

As the economics of recovery is the quintessential component of producer interest in take-back legislation, producers would also like to be able to influence it by designing products for recovery. A critical impact on the CLSCs is observed in this aspect. Product take-back legislation usually does not give enough incentive for reuse options [8,11]. First, since remanufactured/reconditioned products are usually targeted for developing markets and such legislation comes with export limitations, the possibility to access those markets is restricted. Furthermore, take-back legislation do not set specific targets for reuse, but rather combined targets for reuse and recycling/recovery. These rates can go up to 80–85% by weight. When such targets exist in the legislation, producers have minimal incentives to design products for reuse, because reuse is a higher-level recovery option and is considered to be quite different from recycling. Thus, product take-back legislation is likely to drive design incentives mostly for recycling and even just for the purpose of reducing the recovery costs.

Lack of standardization in take-back legislation and their implementation across different countries impose additional challenges for producers, in particular for those operating in multiple international markets. Such global producers have to deal with differing policies, financial and operational structures, and come to grips with immensely complex and diverse administrative structures. On the brighter side, the legislation induces producers operating in regions with no existing legislation to comply with these rules in order to export their products. This is likely to have positive spillover effects on their local markets as well.

Processors/Recyclers

The stakeholders that mostly benefit from the existence of take-back legislation are probably the recyclers and waste treatment and processing firms (henceforth referred to as recyclers). Clearly, take-back legislation with recycling and recovery targets brings additional business to these firms. This is evident also from the recent growth of the recycling industry. According to International Association of Electronics Recyclers,

the number of WEEE recyclers in the United States (500 recyclers and 19,000 employees in 2005) increased about 10% between 2003 and 2005 (www.iaer.org).

From the recycler's perspective, there is a growing stream of products that are being retired by end users, which have to be recycled. Before take-back legislation came to effect, recyclers would have preferred to process products or material that had high recovery value to have high profit margins. Current legislation (for both ELV and WEEE) allows recyclers to process products or new material with less recoverable value at sufficiently high margins, because there is someone paying for the cost of recycling.

Nevertheless, take-back legislation comes with certain duties and standards. Recyclers are often responsible for tracking the amount of processing they conduct and regularly report to administrating bodies. They also have to meet strict environmental standards relating to the storage, treatment, and recovery of end-of-life products to maintain authorized status. Furthermore, these standards are likely to tighten in the future. For example, while shredding is an acceptable form of recycling in the case of electronics, it may not be so in the future. Consequently, from the recyclers' point of view, investing in R&D and looking for superior recycling technologies may be essential for future profitability.

Remanufacturers

Take-back legislation has significant effect on third party remanufacturers. Given that most legislation comes with collection and recycling targets, producers have a vested interest in getting access to the used products with their own brand name. Consequently, it seems quite probable that third party access to end-of-life products will be harder in the future.

Furthermore, as we discussed earlier, exporting used products out of the country for secondary resale markets is getting more difficult due to raised awareness against exporting of waste. This may lead to reduced business opportunities for third party remanufacturers, especially in the electronics sector.

RESEARCH PROGRESS AND NEEDS

In our preceding discussion, we have highlighted the impact of take-back legislation on CLSCs based on our understanding of the existing legislation. We believe that there is a need to investigate these issues in further detail. The current academic research in this area is at its infancy. The existing operations management literature is mainly concerned about how such regulation impacts producers' operational choices and how the economics of recovery would have a bearing on their profitability.

There are two generic modeling approaches regarding product take-back and its impact on CLSCs. The first class of models is economic in nature, and includes different stakeholders and governments as decision makers. Atasu *et al.* [8] use this approach to take the first cut on how production economics would be affected by target-based take-back legislation. They discuss how recovery targets should be jointly based on recovery economics and environmental impact of products. Further, they show that intense competition leads to higher recycling and collection target requirements. Jacobs and Subramanian [12] take this one step further and discuss the possibility of sharing recovery costs within supply chains. They show that the sharing of take-back related costs between supply chain members (e.g., between producers and suppliers) can indeed increase supply chain profits, and under certain circumstances the social welfare.

The second class of models takes into account operational aspects as well. This part of the literature investigates how strategic and/or tactical decisions related to closed-loop operations, such as product design, CLSC structure, and coordination, would be affected by take-back legislation. Toyasaki *et al.* [6] model and compare collective (monopolistic) and individual (competitive) take-back schemes when collection, recycling, and treatment costs display scale economies. Assuming that target collection and recovery targets are met, they derive and compare equilibrium recycling fees, product prices, and recycler and producer profits.

They show that a win-win outcome can be achieved under the individual competitive scheme for the consumers (lower prices, higher surplus), producers (higher profits), and recyclers (higher profits). An exception to this occurs when the product substitutability is high, in which case the recyclers prefer the collective scheme since the nonprofit organization shields them from the highly competitive producer market.

Several studies investigate the impact of legislation, and in particular the minimum collection and recovery target rates, on CLSC network structures and costs. Hammond and Beullens [13] model a CLSC network of producers and consumers assuming diseconomies of scale in operational costs, and study the impact on prices and product flows. They find that minimum recovery targets can stimulate reverse supply chain activities, but are not sufficient to reduce virgin material and landfill use. Using a more detailed CLSC structure, Walther and Spengler [14] estimate the impact of WEEE Directive on reverse supply chain network and cost structures utilizing data from Germany. They show that transportation and disassembly costs increase (and hence marginal revenues decrease) significantly as the targets for recycling and recovery are elevated. In a similar vein, Quariguasi *et al.* [15] study both the economic and environmental impact in a multiple-objective framework taking European pulp and paper sector as the background, and show that mandatory recycling targets may deteriorate the efficient frontier. Krikke *et al.* [16], on the other hand, study the simultaneous CLSC network design and product design considering both economic and environmental effects. Applying their mathematical model on a data set for refrigerators, they find that the effects of minimum recovery rates are ambivalent; they reduce waste but increase energy use and costs. They emphasize the need to enhance product return rates and feasibility of recovery.

There are other papers that investigate the impact of take-back legislation on product design related issues. Zuidwijk and Krikke [11] explore two possible responses to legislation, product eco-design versus new recovery

processes, and show that investing in eco-design is preferable but has delayed effects. They conclude that legislation like the WEEE Directive in EU is appropriate in the sense that they stimulate recovery, but more incentives are needed to reward eco-design efforts. Atasu and Subramanian [17] study the environmental design incentives provided under take-back legislation and show that individual producer responsibility models create superior design incentives compared to collective producer responsibility models. Subramanian *et al.* [18] bring the supply chain considerations in the picture and investigate how take-back legislation drive product design and supply chain coordination. Plambeck and Wang [19], on the other hand, look at the impact of legislation on the rate of new product introductions in a competitive market. They find that the frequency of new product introduction depends on the specific form of producer responsibility in the legislation.

It is apparent from this brief review that there are large gaps in the current operations management literature. While some research streams consider the impact of take-back legislation on social welfare and producer profits, others deal with operational issues as well. A unifying research framework is needed and this framework should provide details on how the legislation impacts *all* of the major stakeholders. Research on the welfare implications of take-back legislation should take a broader perspective and identify the impact on these stakeholders. Similarly, the stream of research looking at the strategic and tactical decisions related to closed-loop operations should consider the specifics of the existing legislation, that is, what is relevant in practice, to identify the important research questions. Bridging the gap between the existing research streams is likely to create a better understanding of the impact of legislation and can result in improvements in the existing legislation from the perspectives of all stakeholders. We believe there are significant opportunities for applying operations research (OR) and management science (MS) methods and tools to resolve these challenges.

ILLUSTRATIVE MODELS

In this section, we illustrate how OR and MS models can be used to study the impact of legislation on closed-loop stakeholders. The first example investigates the economic and welfare implications of legislation, whereas the second example includes operational aspects as well.

The first model is based on Atasu *et al.* [8]. Economic models investigating welfare implications of take-back legislation usually include a typical utility structure for consumers, for example, consumer valuations (θ) for the product of interest are uniformly distributed between 0 and 1. Given the associated recycling fee (say ρ_c) and sales price of the product p , a consumer with valuation θ for the product gets utility $U = \theta - p - \rho_c$. In this case, the demand for the product can be developed as $d = 1 - p - \rho_c$, as a function of the sales price and take-back fees charged to consumers. As an illustrative example, consider an integrated producer (who represents distributors, manufacturers, collectors, and recyclers) who anticipates the consumers' response and tries to maximize his/her profit $\Pi = (1 - p - \rho_c)(p - \mu - \rho_m)$ with respect to the sales price p , where μ is the marginal production cost and ρ_m is the take-back fee charged to producers. The producer optimally chooses the profit maximizing price $p^* = (1 + \mu + \rho_m - \rho_c)/2$. At this optimal price, the sales quantity would be $q^* = (1 - \mu - \rho_m - \rho_c)/2$. In this case, the producer profit will be realized as $\Pi(p^*) = (1 - \mu - \rho_m - \rho_c)^2/4$ and the CS can be calculated as $CS = q^{*2}/2$. Given the producer's optimization problem, the social planner (government) tries to maximize the social welfare that consists of producer profit (Π), CS in the economy, and possible environmental externalities (E). Modeling the environmental externalities is a challenging task, because multiple factors, such as level of consumption, virgin or recycled material use, disposal amounts, recycling amounts, or recycling technologies, may be affecting the environmental impact of production and take-back. The typical trade-off the social planner faces is between the economic surplus (e.g., $\Pi + CS$) and the externalities,

where the economic surplus decreases and the environmental externalities (e.g., environmental benefits) increase with higher fees (ρ_c and ρ_m). Finally, the task of the social planner is to choose the optimal levels of ρ_m and ρ_c , such that the social welfare is maximized. For details of such a procedure under alternative cost structures, legislative implementations, or competitive settings, we refer the reader to Atasu *et al.* [8]. Note also that such models can be further developed to take into account the existence of disintegration in CLSCs, for example, how does the welfare change if producers, distributors, collectors, and recyclers are not integrated?

The second model is based on Toyasaki *et al.* [6] and compares the two prevalent implementation forms of take-back legislation—collective and individual responsibility—in a competitive setting. Suppose that the market consists of two (groups of) producers indexed by $j = 1, 2$ and two (groups of) recyclers, indexed by $i = A, B$. The demand in the product market is given by $d_j = \alpha - p_j + \beta p_{3-j}$, $j = 1, 2$ where α is the market size of each producer and $\beta < 1$ is the cross elasticity of demand. A given fraction τ of the sales are collected and sent for recycling and treatment. The unit recycling fee charged by each recycler is t_i , $i = A, B$. In the collective scheme, there is a nationwide nonprofit organization which is responsible for allocating the waste for recycling and treatment and charging the resulting costs to the producers. Suppose that the nonprofit organization employs a fixed allocation rule, where Recycler A gets a fraction of λ and Recycler B gets the remainder $1 - \lambda$ fraction. The nonprofit organization then calculates the average recycling fee $t = \lambda t_A + (1 - \lambda)t_B$ per unit collected to each producer. This ensures that the cost of recycling and treatment is borne by the producers according to market share and the nonprofit organization makes no profit. In the individual scheme, each producer makes an exclusive contract with a single recycler. Without loss of generality, Producer 1 bears the unit fee t_A set by Recycler A and Producer 2 bears the fee t_B set by Recycler B.

The strategic interactions between the CLSC stakeholders can be modeled using

a two-stage noncooperative game. At the second stage, producers simultaneously set the product prices to maximize their profits based on the recycling fees. Letting c denote the unit production cost (same for both producers), Producer j 's optimization problem in the collective scheme is as follows:

$$\begin{aligned} \max_{p_j} \pi_j = & (p_j - c)(\alpha - p_j + \beta p_{3-j}) \\ & - t\tau(\alpha - p_j + \beta p_{3-j}). \end{aligned}$$

For the individual scheme, Producer j 's problem is same as above except that the fee t is replaced with t_A for $j = 1$ and t_B for $j = 2$. For a given pair of recycling fees, π_j is concave in p_j , so there is a unique Nash equilibrium product prices $p_j(t_A, t_B)$. Based on these prices, the demand for each producer, and hence the amount of WEEE $w_i(t_A, t_B)$ destined to each recycler can be derived for both schemes. In the first stage of the game, the recyclers simultaneously select their unit fees taking the resulting producer prices and WEEE amounts into account. Let r denote the unit revenue earned from recycling a unit. The total logistic, processing, and treatment cost is taken as $(\eta w_i(t_A, t_B) - \theta w_i(t_A, t_B)^2)$, where η is the unit cost without economies of scale and θ is the economies of scale factor. Then Recycler i 's optimization problem can be formulated as

$$\begin{aligned} \max_{t_i} \pi_i = & (t_i + r)(w_i(t_A, t_B)) - [\eta w_i(t_A, t_B) \\ & - \theta w_i(t_A, t_B)^2]. \end{aligned}$$

Under mild conditions, π_i is concave in t_i , hence unique Nash equilibrium recycling fees (t_A^*, t_B^*) can be found for each scheme. The resulting equilibrium producer prices can be derived from the first stage game as $p_1^* = p_1(t_A^*, t_B^*)$ and $p_2^* = p_2(t_A^*, t_B^*)$. Comparing the equilibria, it is possible to derive conditions under which each scheme is preferable for each stakeholder. The model can be extended to the case where there is asymmetry in market sizes, operational costs, and economies of scale factors, as well as to the case where the recyclers directly compete for WEEE allocation in the recycling market. We refer the reader to Toyasaki *et al.* [6] for details.

CONCLUSION

It is evident that the take-back of end-of-life products is a vital instrument for environmental sustainability. The importance of this is borne out by the number of existing and planned take-back legislation. Interestingly, the organization and financing of these activities show disparity across different implementations, and there are diverse views regarding the preferred system. Likewise there are conflicts of interest among various stakeholders. These signify the importance of taking a holistic approach and addressing the impact of take-back legislation from a comprehensive, multiple-stakeholder- and multiple-objective perspective. To the best of our knowledge, existing literature has not yet accomplished this. The interactions between these stakeholders need to be identified and research on coordination between stakeholders is essential to determine the best case scenarios both from the industry and social points of view, considering the triple-bottom line impact—people, planet, and profits. In addition, a detailed investigation of product design implications of take-back legislation is also needed. While the existing legislation is usually local, we believe that its global impact should also be a concern for academics.

This article is aimed at providing an overview of existing take-back legislation, its impact on CLSCs, determining the pressing research issues, and illustrating how OR and MS tools can be applied to examine these research issues. We provided our perspective on the eminent effects of such legislation to the best of our knowledge, but we acknowledge that there surely exist other possible impacts that are not yet readily observable. We also realize that further research is needed to verify some of our arguments. This calls for a strong interaction with the industry and data-driven (empirical) research.

TEACHING ORMS/ANALYTICS WITH CASES

MEHMET A. BEGEN
SRINIVAS KRISHNAMOORTHY
JOHN WILSON
Richard Ivey School of Business,
University of Western Ontario,
Ontario, Canada

INTRODUCTION

Traditional methods for teaching Operations Research/Management Science (ORMS)/Analytics and Management Science/Operations Research have focused on the lecture model for delivery of content. This often gives rise to students being technique oriented and unable to apply the material in situations encountered outside the classroom. A major goal of the case-based approach is that students become able to identify top-level issues and apply models to situations not necessarily encountered in the classroom.

Case teaching can be implemented gradually in a traditional lecture-based *ORMS/Analytics* course; in fact, instructors can use cases in tandem with lectures. Cases can also be the core pedagogical methodology for a course.

THE CASE METHOD

The case method is an interactive style of learning. In traditional lectures, the instructor delivers a prepared talk or presentation, while the case method requires that the “talk time” be shared among the students and the instructor. The instructor’s role is to prompt students to express their opinions and conduct the discussion. Specific activities include initiating the discussion with initial questions posed to the class, selecting a student when a bunch of them raise their hands, listening to students’ comments, and responding to and amplifying comments. The

response may include a direct response to the student, probing the student for a clarification or even redirecting it to the class. A wrap up may also be required at the end of class. The case method applied to *ORMS/Analytics* poses some unique challenges. We explore those challenges in later sections but first we take a look at some articles that explore case teaching for *ORMS/Analytics*.

Many case instructors have presented their ideas on the use of cases for *OR/MS* and *Analytics* courses. Aggarwal and Khera [1] discuss the benefits of using short cases for teaching introductory management science courses. Highlighting the heterogeneity in quantitative skills among their MBA students, they argue that a case-based course works better than a traditional course. Furthermore, they believe that cases should be short and managerial in order to keep the student’s interest alive. Martin [2] supports the views of Aggarwal and Khera but argues that there is a group of business students who will benefit from pure OR in addition to managerial cases. He refers to them as model builders (as opposed to managers who may use models developed by others). Horner [3] interviews Peter Bell, Professor at the Richard Ivey School of Business, to understand the benefits of teaching OR/MS using case studies. The article is wide ranging in the perspective it offers on incorporating OR/MS cases in the business school curriculum. Bodily [4] describes how the Quantitative Analysis course at The Darden School of Business has been designed to integrate with the other MBA courses. Specifically, by using a case-based approach, the quantitative analysis teaching team at the Darden has managed to create a decision-based course rather than a “quant” course. This same principle has been adhered to while designing the quantitative analysis electives at the Darden. In similar spirit, Liberatore and Nydick [5] provide a description of their MBA Management Science course at the Villanova University. Bell and Haehling

von Lanzanauer [6] illustrate the benefits of exposing students to a real-life business problem by discussing their experience in the classroom with using a particular case study. Cochran [30] provides a detailed description of the case methodology that he adopted for teaching operational research to undergraduate business students. Hannibalsson [7] discusses how he has incorporated cases, games, and other active learning techniques in his operations course at the University of Iceland. Schmedders and Stephens [8] urge the development of new OR/MS cases that reflect current business problems. As part of his insights on teaching OR/MS to Executive MBA students, Bell [9] describes the benefits of using cases and offers specific examples of cases that he uses in the course. Long [10] shares his experience in teaching operations research using cases and presents his perspective on the requirements for successful implementation of this methodology. Cochran [11–13] provides detailed illustrations of how he has successfully used a particular case in the classroom. In his review of OR pedagogy, Cochran [12] enumerates the effectiveness of case teaching and also lists the different business schools that have adopted this approach. As part of his article on making classroom learning memorable, Cochran [14] discusses how his adoption of case-based teaching improved the student experience because of more personalized attention associated with the new teaching method. Moving from management science to other disciplines, Liang and Wang [15], Kim *et al.* [16], and Currie [17] provide perspectives on case teaching. Our goal in this article is to reinforce the ideas discussed in the above articles while adding some of our own perspective to the art of teaching ORMS/Analytics with cases.

There is empirical evidence that case teaching is more effective than lecture teaching in business education. Specifically, Bocker [18] has conducted a field study to confirm this hypothesis. Our goal in this article is to not dismiss lectures as an outdated method of teaching. We believe that cases and lectures can go hand in hand to offer students a variety of learning

experiences and instructors a variety of teaching experiences in the classroom.

Case-based teaching has spread from the traditional case-based schools of Ivey, Harvard [32], and Darden [31] to many other schools. Moreover, it is being implemented in a variety of ways, for example, a combination of case- and lecture-based teaching and mini cases. A number of universities have case publishing arms—prominent among them being the Ivey [33], the Harvard [32], and the Darden [31]. In addition, *INFORMS Transactions on Education* (Available at <http://www.informs.org/Pubs/ITE/>) publishes teaching cases online and INFORMS organizes an annual case competition (Available at <http://www.informs.org/Community/INFORM-ED/Activities/Case-Competition>) since 2000. Other sources include the ECCH (European Case Clearing House), (Available at <http://www.ecch.com/>) and *The Operations Management Education Review* (OMER) (Available at <http://www.neilsonjournals.com/OMER/>).

A CASE-BASED COURSE

It is certainly possible to use only a handful of cases in a predominantly lecture-based course. However, in what follows, we describe a case-based course. The comments and suggestions also apply if an instructor is simply using a few cases to illustrate and apply concepts from lectures. In this case, an instructor might decide to use an integrative case that requires students to use a number of different techniques to arrive at a decision or might decide to use cases that require knowledge of any a few techniques or both.

We suggest positioning a course as using the art of using data and models for decision making, with the emphasis being on decision making. For instance, such a course could be structured around “modules” such as

- Foundations of modeling;
- Models for sequential decisions;
- Data and decision making;
- Models for managing risk;
- Models for simultaneous decisions;
- Models for revenue management and pricing.

Each of these modules focuses on traditional OR/MS topics such as statistics, decision analysis, probability, simulation, and optimization. For instance, “Models for sequential decisions” refers to decision analysis. We prefer to use “business” names rather than traditional technical names for our modules. We find that students relate to our material better when there is a managerial implication, and this applies to module names as well. We have found that our course name at The Richard Ivey School of Business “Decision Making with Analytics” (DWA) can have more traction than traditional OR/MS names with both students and our other management colleagues. One model for covering the material is presented in Figure. 1. The first column refers to cases that require only one or two modeling techniques. Cases in the second column are more difficult and generally require more than one quantitative technique. The final column refers to complex integrative cases that very closely mirror the real word.

For examples of basic cases, we have ones that cover regression models for real estate price prediction, solution of newsvendor problems via simulation, product mix cases that require simulation. For instance, we can use the traditional case *Red Brand Canners* [19] to introduce linear programming. In addition, we use complex cases—especially for multiple regression—that use only one main technique. For example, the cases *The Professor Proposes* [20] and *Lanksink Appraisals* [21] are useful to tie a number of statistical

ideas together. At the final level, when the students have mastered the basic techniques, we use a number of complex cases in revenue management and the pricing of contracts and real options that not only test students’ analytical abilities but also open their minds to the applicability of the material. Some of our favorites here have been Enron Corporation’s Weather Derivatives(A) & (B) [22], Jaikumar Textiles Limited (A) & (B): The Nylon Division [23], Kimpton Hotels: Setting prices on Priceline(A), (B) & (C) [24], The Clonlara Hotel [25], and Seoul National Bank: The Chief Credit Officer’s Dilemma [26].

DWA CLASS IMPLEMENTATION

We implement interactive discussion-based case teaching. Our strategy is to let students learn by doing. The easiest way to make any class interactive is to simply ask students’ opinions on a topic rather than lecturing about one’s own ideas first. From time to time, when we feel necessary, we deliver minilectures in class to highlight important points, give an overview of the topic we are studying, or clarify concepts. For instance, we usually give a short introductory lecture on linear programming.

Teaching ORMS/Analytics interactively with case discussions may look difficult at first, that is, teaching a quantitative topic to students especially to ones who have no background in math, statistics, or any other quantitative fields. We start with a simple

Figure 1. Case types.

case application whenever we introduce a new topic. For instance, consider regression. We give a short lecture on how to run a simple linear regression model—we take two variables, plot and fit a line. We assign introductory background readings from a textbook. We then use a case that requires the students to develop a simple linear regression model. Once this is done, we demonstrate the technique of adding extra variables and assign some more rudimentary readings. We do not comprehensively cover all the complexities of regression. (This is one of the trade-offs of the case method—depth in a technique is sometimes sacrificed so that students better understand how to apply the methods and contemplate top-level issues.) The next case is a step up in the level of challenge and could require the development of a multiple regression model. Students are required to peruse accompanying readings. We continue in this manner raising the difficulty level. This is illustrated in Table 1.

At this stage, students now have gained enough technical skills to tackle complex regression cases with regression.

When applicable and appropriate, we use related research papers or newspaper articles (e.g., a research paper relating CEOs birthdays to performance in Fortune 500 companies) to motivate the current topic (e.g., regression), show how it works in practice, and strengthen the overall understanding.

We sometimes invite guests (e.g., sometime from the organization in the case or an industry expert on the current topic) to provide additional insights and learning points.

Student Motivation

In order for students to take the process seriously, it is important that class contribution be one of the most important parts of the grade. It should be graded on an individual basis, and we have found that making it worth roughly one-third of the entire course mark is effective.

Before Class

Students are expected to attempt the case as part of their homework. There are assigned questions for each case. Student preparation involves more than simply reading the case.

Table 1. Teaching Framework with Cases and Minilectures

Order	Events	Content
1	Minilecture 1	A Y -variable (e.g., house prices) An X -variable (e.g., square footage) Plot variable in Excel Fit line on plot and obtain an equation for it Discuss the idea of an equation to predict house prices as a function of square footage Assign a reading on (simple linear) regression
2	Case	Simple case with two variables Class discussion and solution approaches Use of regression equation to solve the case and obtain insights Introduction of ideas on R -squared, residuals, and p -values
3	Minilecture 2	Demonstrate how to add new (multiple) X -variables Discuss why more than one X -variable may be needed: other factors, indicator variables Extend the example from Minilecture 1 to multiple variable regression Provide a reading on multiple regression
4	Case	Slightly more complex case with more variables Class discussion and solution approaches Discussion of R -squared, p -values, residual plots, and transformation of variables Use of regression equation for the case

A proper preparation includes perusing the case, preparing answers for the assignment questions, and finally, building and using a model to make a decision. It is very important that students attempt the case by themselves before talking to others—otherwise only limited learning will take place. After they complete their individual preparation, they discuss the case in a small group setting. This small (study) group usually consists of four to six students who come together before the class to exchange notes and ideas. The small group discussion serves as a dry run for the big group (class) discussion. The stakes and anxiety level are a lot less. Students are only within a small numbers of peers; there is no instructor present, and their performance is not graded. It is an opportunity to strengthen their understanding and preparation for the classroom discussion.

During Class

Start the class with a start-up question. In general, this should be a question that can be answered without any technical knowledge. This allows all students to feel that they can contribute irrespective of their backgrounds or trepidations about some of the later technical aspects of the case. A good example of a start-up question is “What specific decision needs to be made?” Instructors will find the answers to this question illuminating. For instance, we can use a product mix case to introduce linear programming. Here, we sometimes say “I will give you any specific numbers you want. Tell me what you want and how would you communicate this decision to those who are in charge of implementing the decision.” Many of the answers we get are along the lines of “Find the ... that optimizes ...” or “Choose values of ... that satisfy the constraints ...” None of these, of course, are satisfactory because they are related to a solution procedure and not to the final decision that needs to be communicated to workers who will actually carry out the decisions. This approach gets students to realize that the output of the case is ultimately a set of specific instructions, for example, take 10 pounds of ingredient A and 15 of ingredient B and make product and take 15 pounds of ingredient A and

3 of ingredient C and make product 2. It is remarkable how difficult this is for students of all backgrounds. This becomes one of the great advantages of the case method, being able to actually make and implement decisions rather than only knowing how to “solve” things.

It is important to carefully manage the first questions. Sometimes, there will be some students who have “solved” the case. If one of these students is chosen and care is not taken in managing the response, the instructor can find that there is not much more to discuss. So the instructor should be ready to limit students’ responses to very specific answers and may collect a number of answers before opening up the discussion around one of them.

Sometimes, the start-up question is one of the assignment questions. The student who is given the floor then provides his/her answer to the question. It is the instructor’s job to acknowledge the answer or probe for more details or even seek the opinion of other students. Sometimes, we make “cold calls,” that is, seek a response from a specific student. We find that this is a good way to ensure preparation because there is no advance warning of who could be selected. We hasten to add that the primary motivation for students to prepare or cases does not come from fear of embarrassment. It is the desire to perform under pressure under the scrutiny of the professor and fellow students. This also helps train student to be effective managers and implementers of OR/MS and Analytics. It does help that we have as much as 30% of the course grade based on class contribution.

Following the start-up question, we raise more detailed and specific questions to direct the discussion. We may use the whiteboard or overhead to summarize ideas, write down equations, or even draw pictures or graphs in order to add conceptual richness to the discussion. Each case requires building some sort of a model. This is typically a spreadsheet model; however, sometimes, it could be just a system of equations or graphs that can be done on the board. If the model can be done by hand (rarely the case) then we build it on the whiteboard or overhead in an interactive manner seeking the help and comments of students. On the other hand,

for a spreadsheet model, we pick a student who connects his/her laptop to the projector. The selected student then builds the model on his/her laptop with the help of other students. We moderate this interactive model building process. When necessary, we provide corrections to the model. Following the construction of the model, we use it to derive insights that are relevant to the problem being solved. The final step is to seek a decision from the class based on the insights provided by the model. Typically, we probe for a justification of any decision that student makes. In addition to the model output, students often bring in qualitative aspects that may affect the decision. Particularly relevant at this stage is the personal experience of a student who has worked in the industry or even the company itself. We end the class emphasizing the conclusions and learning points. In the next class, we may offer a brief review of the learning points of the previous case.

We find that the spreadsheet models are powerful for what-if analysis. Our students enjoy the insights that the output of a model provides. In the initial part of the course, students find it difficult to create a model or even conceptualize the trade-offs that a decision-making situation entails. However, this changes over the course of the semester. Students become more refined in their thinking and their ability to construct models.

We also allow room for students to share their own models. Sometimes, at the end of the class, we may ask a student to share his/her model if he/she adopted a different approach. We also allow students to post their developed models on the university's intranet so that each student in class can have access to it.

It can be important to have a clear and concise wrap-up for the case. Of necessity, the case method will involve lots of twist and turns and barking up the wrong tree. This is part of the learning process. However, many students have been conditioned to believe in a "right" solution. It can be very frustrating for them not to see a clear path to the conclusions. It is, however, important to emphasize that it is rarely possible to jump to a clean "solution." In addition, it is important to emphasize that the solution is only

as good as the inputs. How robust is the output to changes in the inputs? Maybe an input distribution is not normal or uniform or whatever. A discount rate is often used in making a decision. How sure is one of this number? What is the risk involved with a decision? Expected values for a one-shot decision can be very misleading if the variability is high. What are the consequences of not hitting the targets implied in a decision? What are the probabilities of missing a target?

A BASIC CASE

Regression analysis is very amenable to a case-based approach. We often start with a case that has time to complete assembly of a certain product as the dependant variable and the independent variables including the number of operations required per product, size of batch, priority class, and so on. An order has just been taken and the salesperson wants to give the client an idea of when the product will be ready.

"Top-Level" Questions

A reasonable starting question is "What number or numbers should be provided to the salesperson?" A number of answers can be collected from the class and written down. Some will want to provide a specific fixed number. Some will want to provide a range. This starts a discussion of risk and expected value and maybe standard deviation. Non-symmetric risk can become a discussion point: "Would you want to overestimate or underestimate the time you provide?" "What are the managerial consequences of underestimating or overestimation?"

Detailed Analysis: Input for Making the Decision

If your production manager tells you that only the number of operations is predictive, how would you go about giving a prediction? The answers from this are very illustrative of the thinking in the class. Many will try to group products in the data set with a similar number of operations and maybe just average them out. Some of the follow-up issues here

are what do we do when there are not many observations with the number of operations close to the product for which we are trying to predict? How do we deal with the issue of risk? Some will say plot the data.

Plotting the data leads to more questions. Many will now see that fitting a line might be the way to go.

At this stage, the question might be raised that other variables should be introduced, and this leads to a discussion of multiple regression.

Flow of the Case: Approach 1

Have the students read the case before but not do any formal quantitative analysis and are ready to discuss. After the discussion, give a short minilecture on fitting lines and multiple regression models with the software being used in the course. Have students do a full analysis after class and are ready to present the next day.

Flow of the Case: Approach 2

Make sure that the students know how to plot, fit lines, and multiple regression either from minilecture or by being directed to appropriate readings. Have them read the case and come up with the best approaches they can. In class, have students discuss and present their approaches. Distill the ideas at the end by having a student go through step by step the process to arrive at reasonable predictions.

A GENERIC INTEGRATIVE EXAMPLE

Consider the following generic example: a one server queue with random service and waiting times. Costs are incurred for waiting. The issue is should another server be introduced? This could incur extra fixed and variable costs. In a case setting, the problem would never be introduced in such a mathematical manner. Instead, the problem would be introduced from a business decision-making point of view. This scenario is close to a number of cases that we use.

“Top-Level” Questions: Making the Decision

The class would be asked a question such as “If you are the CEO, what crucial number or numbers—no more than two or three—would you want from an analyst/a consultant who is advising you on whether or not to invest in a second facility?” This is a question that everyone—no matter what their backgrounds—should be able to attempt. Many of the answers we get are illustrative of how students struggle in finding what is important. Some of the more popular answers we get are as follows:

- The current average waiting time;
- The current average idle time;
- The throughput;
- The work in process;
- The total current waiting time cost.

It is remarkable how difficult it is to get students to arrive at the most important issue, that is, how much more profit would be made if a new facility (server) were introduced. Then, it is even harder to obtain what needs to be calculated to obtain the answer to this question—that is, some measure of the gain in profit between the current system and the one with the new facility. Some numbers that might help if one were looking at one period would be

- expected profit for current system;
- expected profit for new system;
- difference between these.

Now suppose that the system is to be in place over a number of periods. How would one make a decision? This leads into a discussion of how decisions are made in reality. Such things as the net present value of the difference in profits between the two systems can come up.

Now, some arbitrary numbers can be assigned before the case is tackled at the OR level. The students are asked what they think about the risk involved. This leads them into asking how to refine the numbers given above and also to talk about what is meant by risk.

Detailed Analysis: Input for Making the Decision

So far no OR/MS or mathematical terminology has been introduced. Yet, in our experience, all students, both those with a good quantitative background and those who eschew quantitative things, find the above incredibly difficult. Yet, the above is often the most important part of any decision-making analysis for which OR/MS methods are appropriate and illustrates the value of the case method approach.

At this stage, one can start to get into the more detailed quantitative aspects. What are the stochastic inputs to the problem? How would one find appropriate distributions? Now, at the microlevel, for instance, one can look at the arrival distribution alone but realizing this will be an input for arriving at answers to the above questions. Distribution modeling, Excel spreadsheet modeling, and simulation will all be important here. The assumption is that cases that have made the students familiar with these techniques have been previously introduced.

Flow of the Case: Approach 1

- Have the students read the case before class but do not have them do any analysis.
- Have a discussion around the top-level decisions.
- Have the students “flowchart” the steps needed for the detailed analysis.
- Have the students present a detailed analysis for the next class that consists of a number of steps:
 - Slides that get straight to the management decision, that is, they should assume that they are consultants and give a “high-level” presentation.
 - Be ready with a detailed flow chart of how the problem was modeled.
 - Be ready to go over detailed analyses of the embedded OR/MS models, for example, precisely how they derived a service time distribution for the data provided.

Flow of the Case: Approach 2

- Have student read and try to “solve” the case before class.
- Have students present their work to the class. Have the class interact with a given solution by asking questions.
- Introduce questions such as the ones discussed above during the presentations and the ensuing discussions.

STUDENT EVALUATION AND EXPECTATIONS

It helps if the instructor assigns a participation grade to each student right after each session. For one thing, the discussion is still foremost in the instructor’s mind. This grade depends on the overall quality of everything that a particular student said in that class. We value a single, strong contribution more than several weak ones—however, quantity also counts for something. The instructor, in addition to her/his own grading, may also use peer evaluation for the class participation. Peer evaluation can be easily done by asking a few students at the beginning of each class to keep track of students who made a comment, as well as choose the ones who they think contributed the most to their learning that day. Marking class contribution is not that difficult in our classes because students sit on the same seat each class and also have nametags. (We change their seats only a few times in a year.) Therefore, there is a seating plan of the entire class that we can use in assigning grades. It also helps to have a photograph of the class because it makes it easier to assign participation marks afterwards. It is important for the instructor to be fastidious in this—often, at the end of a semester, students will try to increase their class mark because they feel they should have gotten a higher mark than others in the class based on their perception of what they said during the semester. Clear records will make the instructors job a lot easier here.

Some of the ways student can participate in class are

- starting off class/case discussion in an insightful way;

- presenting and developing models;
- advancing the comments of others;
- providing constructive criticism;
- emphasizing learning points;
- sharing personal workplace experiences from similar situations.

Grading class contribution is one of the most important aspects of interactive case-based teaching. It motivates students to come prepared to class. For example, by quick and simple questions to randomly selected students (i.e., by cold calls), the instructor can test whether students did the assignment readings and studied the case. This is an effective way of ensuring that students come to class prepared. Furthermore, we believe class contribution pressure helps students to improve their communications skills in business situations and helps them to develop public speaking skills, which is a fundamental requirement in business. Finally, grading of class contribution increases the quality of discussions and improves the overall learning and education experience of students.

For us, other components of student evaluation are quizzes, a midterm, and a final examination. We usually conduct a midterm or quiz to test the techniques and concepts taught in class. We design the examination to contain various types of questions (e.g., multiple choice, quantitative problems, true/false). On the other hand, the final examination is always a case examination. Depending on the instructor's choice, it could be either an individual hand-written examination or a take-home examination. If it is a take-home examination, we often conduct it as a 48-h report to be prepared in teams.

We expect students to be fully engaged in the entire learning process, that is, devoting time and energy to preparation before class, including small group meetings, listening to others during class discussions, and engaging in class discussions. Student participation is the key for our interactive case-based learning and teaching.

We acknowledge that the *ORMS/Analytics* subject may be difficult for some students, but we expect every student to attempt the cases on their own first. We

believe that it is okay not to be able to do the analysis correctly, but it is not acceptable to come to class unprepared. We communicate this philosophy to the students early in the semester. Lastly, we expect our students not to discuss any future cases (the ones not yet covered in class) with anyone other than their own classmates.

ADVANTAGES OF TEACHING ORMS/ANALYTICS WITH CASES

Case teaching is an interactive style of pedagogy that is in direct contrast to the traditional lecture style of teaching. Being a “science-” and “content-” based subject, *ORMS/Analytics* has conventionally been taught using lectures. We appreciate the value of lectures, and in fact, use minilectures in our classes at Ivey. Lectures allow us to transfer “fact/formula”-based knowledge to our students. On the other hand, we believe that case teaching enables “concept”-based learning. In our opinion, the best way to learn a concept is to apply it in a real-world setting, which is precisely the experience that cases provide. We structure our classes so that students attempt the cases individually before they arrive for class. In class, we orchestrate a sharing of ideas and coordinate a joint solution approach to the case problem. We believe that there are a number of advantages to this style of learning.

Students attempt to solve the case as part of their homework and often struggle to formulate a solution. This is an important part of the learning experience. We feel that students are more likely to remember a concept if they struggle a bit while learning it. Furthermore, cases usually enable students to take different sides and have dissimilar opinions on importance level of issues, effectiveness of solution methods, practicality of proposed solutions, and many others. This provides an excellent opportunity to see other views and new ways of thinking on the same case/problem. The class discussion requires students to be mentally alert and active so that they can contribute their ideas and opinions. They are more likely to be engaged in a case discussion as compared to a lecture that

requires them to be passive listeners. (Recall that we have as much as 30–35% of the grade based on class contribution that provides an incentive for students to participate in the case discussions.)

Cases are a great way for students to pull different concepts together and learn “integrated analytics.” For instance, we teach a case titled “Four Star Motorsports” [27] that requires the student to develop a pricing plan for selling tires over a season. The demand for tires is predicted using regression, and then the students apply optimization to choose the best set of prices to sell the fixed inventory of tires. Such integration of *Analytics* concepts has elicited favorable responses from our students.

Case teaching is rewarding for the instructor as well. Two class discussions of the same case are seldom alike. Unexpected surprises and unusual points of view abound in case discussions. We have personally enjoyed the mental stimulation that case teaching provides. It is exciting to stand in a theater-style classroom and direct the flow of ideas. Often there are students in a class who have practical experience that is relevant for the case discussion. Other students find this sharing of colleagues’ experiences to be a great motivator and help bring out the relevance of the material.

CHALLENGES OF TEACHING WITH CASES

The prospect of teaching cases is intimidating to many instructors—especially rookies. Case teaching requires the instructor to relinquish a degree of control over proceedings, which is a terrifying prospect for instructors who are used to delivering a prepared lecture.

Students from all backgrounds have difficulties with the case method. Those from a nonquantitative background tend to eschew anything quantitative. Surprisingly, they also find the “top-level” questions difficult because they require a certain formal discipline in how one approaches questions and makes decisions. Those from a quantitative background often want to run straight to modeling and often the wrong modeling. They tend to have too much faith in the models and the numbers and fail often

to realize that the models are only as good as the inputs. They also tend to find the “top-level” questions extraordinarily difficult.

This does raise issues for the instructor. In schools where evaluations are the most important part of the teaching experience, raising discomfort levels for students of all backgrounds can be problematic. As the course progresses, it is important to demonstrate to students that this method gives them superior analytical and decision-making skills that will be useful in very practical ways in their careers.

Substantial preparation is required for teaching a new case. The good news is that reteaching the case is much easier. Preparation includes not only knowing and solving the case and making a class plan ready but also familiarizing with the case teaching environment. Before your first case session, watching a few live case discussions would be of great help. Another way to get familiarized with the case method is to read about it [28]. The instructor has to be comfortable with students expressing their views—some of which may not be entirely correct or practical. The onus is on the instructor to listen, provide feedback to the student, and then “repackage” the student’s views for the rest of the students in class. This requires the instructor to be constantly present in the moment and exercise sound listening skills. Our experience has been that teaching cases is far more mentally draining than lecturing. Of course, this makes teaching more enjoyable as well.

Case teaching is not a good way to cover “content.” We use minilectures for that purpose.

As discussed in the previous section, often, it can help different sides in the class discuss a case. For instance, those who rush to a mathematical answer can be quizzed by students who are told to take the role of a consumer of information and ask probing questions about the practicality of the approaches. Those who want to go with a “gut feel” approach can be quizzed by other section of the class on some important managerial but very quantitative related issues. (“You say we should invest in your portfolio and that you expect to make a \$32 return. What is the probability the return will be

negative?” Of course, a good response to such questions requires that a model be run.) This banter and to-and-fro discussion (if tightly managed) can be one of the most interesting parts of the case discussion. Students start to focus on the material and how it needs to be presented and explained to their peers rather than as an academic exercise or something that will satisfy their perceptions of what an instructor wants.

The instructor will often have to deal with negative feelings of students who struggle with the cases that simulate unstructured decision-making situations experienced in real life. It is the instructor's responsibility to support the students and advise them on the benefits of learning through struggle. One effective way to calm down these students is to remind them that they will face similar unstructured difficult business situations in their career and future life and will need to make a decision then, and the sooner they can learn the better. Furthermore, we also tell our students that our classrooms and cases provide them a laboratory-like environment in which they can learn real-world decision making by making mistakes (with no cost and with no risk), learn from others, develop their skills, and build their confidence. We frequently remind our students that doing (especially management science) cases and learning from them is a nonstop process and everyone can get better at it. We tell students that learning doing/solving cases is like learning a sport, for example, swimming or playing tennis. Unless you put some effort, time, and will power, you will not learn it and you cannot learn it by just reading or going over the notes, you should practice it: attempt to solve cases, prepare for class properly, build models, discuss with your stud group, and participate classroom discussions.

Classroom discussions can get heated—especially when students challenge each other. The instructor has to maintain civility of discussion, which is an extra responsibility. Much of the ability to control a classroom comes from experience. We explore this in the section “Becoming a Good Case Teacher.”

It is the nature of the case method that once in a while (and sometimes frequently)

the class discussion will not go in the intended/correct direction, that is, it will bark up the wrong tree. The instructor should be aware that this is part of the learning and let the class go with its own way for a while. Most of the time, somebody in class will realize that they are headed in the wrong direction and change the discussion. And at other times, when no one realizes this or if the discussion is taking too long, the instructor should help the class to find the right path. One easy way to do this is to raise a question that has an answer pointing the right direction or ask a question that makes student think that they need a direction change, for example, anyone has a different/fresh idea/point of view?

Some instructors find it difficult to handle the negative feedback of students who struggle while attempting the cases on their own. Our experience has been that in the early stages of the course, students frequently approach us and express their frustration. However, they adapt over the course of a semester and realize that the struggle is a part of their learning. The case instructor has to be patient and offer gentle encouragement.

It usually helps to sit down with a struggling student and ask them how they had prepared for one of the previous cases. We usually find that insufficient preparation is to blame for unsatisfactory learning experience. From time to time, we also discuss and go over past cases with the students who had questions about them. To encourage noncontributors and frustrated students, we “warm call” them, that is, we inform them in advance of a class that we will call them for that specific case/class. This helps them to motivate and prepare for that class, and once they participate in class, they contribute to contribute in the future classes.

Classroom logistics can often be an issue. Ideally, case discussions require a theater-style classroom with stadium seating. However, this is not a disqualifying requirement. An enthralling discussion is what keeps students engaged.

Case teaching requires cases that are compatible with the teaching objectives of the course. This can be challenging sometimes. Cases can be obtained from schools such

as Ivey, Harvard, and Darden or textbooks. Another way to find cases is to write cases [29], and in fact, those cases can be the best cases to teach because as the writer of the cases, you know the case inside out and its learning/teaching objectives.

BECOMING A GOOD CASE TEACHER

Case teaching is a skill that can be learnt. It requires a period of apprenticeship in the hand of a mentor—someone who has had experience in teaching ORMS/Analytics using cases. In addition, we feel that the following will help:

- *Field Experience.* Much learning happens by actually conducting case discussions. We suggest that the apprentice be “process” oriented rather than “outcome” oriented. There will be some initial struggle, but the learning curve is steep.
- *Observing Good Case Teachers.* A lot can be learnt by watching a good case teacher facilitate a discussion. Having said that, we caution that the apprentice must not blindly copy the style of the mentor; it is important for the apprentice to develop his/her own unique style.
- *Reflection.* We recommend that the apprentice should spend some time after every class, recollecting the case discussion and evaluating the good and the bad. We also recommend that the apprentice should invite more experienced instructors to his/her class and request feedback on his/her class performance.

CONCLUSION

We have found that cases are a very effective method of enhancing ORMS/Analytics in introductory business courses. There are differences, however, between undergraduate business and MBA-level courses: frustrations can be higher for students who are less mature and have weak quantitative backgrounds. Executive MBA courses that we

have experienced are also different—there the focus needs to be much more on the top-level skills and less on the quantitative details. Course outside of business schools and higher (technical) level electives in a business school may require slightly different approaches. For instance, a course on Markov Chains requires substantial analytical and lecture content. However, cases interspersed at strategic point or toward the end of the course can substantially improve students’ abilities to focus on top-level issues related to the material.

Case preparation and discussion stimulate learning by doing for students, and case teaching can be rewarding for instructors. In order to start using cases, one does not need to give up lecturing; a hybrid teaching (a combination of cases and lectures) can be adopted. Each instructor can choose his/her comfort level and course/students needs in a wide spectrum of case teaching environments, that is, from a single case use in a course to a course where there is a case in each class. Case teaching is a skill that can be learnt and one can start using cases adding a single case to their course and go from there. Whether you consider cases as the side dish or the main entrée, they will add spice and flavor to your students’ learning and your teaching experience.

TEACHING SOFT OR/MS METHODOLOGIES: WHAT, WHY, AND HOW

FRAN ACKERMANN
Curtin University, Perth,
Western Australia, Australia

INTRODUCTION

Management Science (MS)/Operational Research (OR) came of age in World War II [1,2] gaining momentum post conflict in organizations seeking to ensure that they adopted a more “scientific” basis [3]. However, while the benefits were acknowledged by businesses, application, particularly in the United States, appeared to be dominated almost exclusively by a quantitative view of the field [4]. This, it is argued [5] is partly due to the editorial policies of US journals and partly due to tenure requirements and also the virtual absence of qualitative methods from teaching [6, 7].

Over time, however, many managers while getting benefit from quantitative techniques such as optimization and so on found themselves struggling to either fully implement the outcomes from the techniques or not getting the benefits they anticipated from them. It has been argued that these issues are likely due to two factors. First, organizations are made up of people and so negotiative approaches are best, and second, problems facing managers are increasingly complex with multiple uncertainties. These observations were made by Ackoff (among others) who argued that the quantitative forms of OR (hard OR) were “mathematically sophisticated but contextually naive” [8], and furthermore that it was important that (OR) was “based on planning with people, not for them” [9]. Ackoff’s propositions stimulated a heated debate within the OR community and resulted in a more wide ranging understanding of OR’s current and potential contribution to improved decision making.

Based partly on this debate, and the work of a range of researchers, the qualitative (soft OR) field sought to incorporate the two factors mentioned above, and a growing appreciation has been gained not only for the soft qualitative approaches themselves but also for approaches that consider human factors and the management of complexity with the more mathematical techniques—recognizing that there is complementarity. This blend of soft/qualitative and hard/quantitative is gaining prominence as evidenced by the growing body of literature around mixing methods [10, 11] as well as the increasing use of combined methods when working on organizational problems [12]. Thus, understanding what constitutes Soft OR and why it is of value is important.

This article therefore explores the realm of Soft OR, considering firstly *what* is Soft OR (and what is it NOT), *why* Soft OR should be taught to students and following on from this *who* should be taught and *when*. This article concludes with some suggestions regarding *how* to teach Soft OR (and thus having answered, what, why, who, when, and how) before reflecting on how best to move forward. In essence, the article adopts Rudyard Kipling’s verse in the Just So Stories regarding the six wise men, simply missing the *where* element (which is to some extent contained within the how and who).

WHAT CONSTITUTES SOFT OR?

Soft OR methods emerged from a growing sense that the traditional “hard” methods were not able to deal with messy [13], complex [14], or wicked [15] situations. Moreover, there was a sense that OR was “losing its way and its self-confidence in the early 1970s—architecture, urban planning and policy sciences all suffered crises” ([16], p. 3) and thus alternative means of modeling were required. Researchers argued that in many cases there wasn’t a single “right” answer—based upon the fact that a number of different perspec-

tives needed to be included, different criteria taken account of, and considerations of sustainability undertaken.

It was also noted that “typically large decisions were not made by a single group of like-minded people . . . they are, rather, the result of extended negotiations, either explicit or implicit between representatives of different points of view” [17] and thus it was important that techniques that thoughtfully address contextual and socio-political considerations were developed. Groups of decision makers needed more support in terms of surfacing, structuring, and exploring knowledge—moving from a divergent explorative position to one that was more precise and detailed in its data and analysis [18]. Researchers recognized that much of knowledge is socially constructed [19] moving from a mechanistic view of an organization to one that recognizes the realities of organizational life with attendant power and politics. Organizations and decision makers needed to move from a basis of muddling through to being provided with the means to make decisions that were both procedurally rational [20] and procedurally just [21].

A range of methods, originating from different fields began to emerge to meet this need, which over time became known as problem structuring methods (PSMs). Rosenhead [22] describes PSMs as methods that seek to help managers deal with situations that “encompassed multiple actors, different perspectives, partially conflicting interests, significant intangibles, and perplexing uncertainties” ([22], p. 759). These methods focus on determining what the problem is, as much as providing assistance to its resolution.

Key contenders for PSM as noted in Ackermann [23] are soft systems methodology—SSM [24, 25], strategic options development and analysis—SODA [26–28], strategic choice [29] as well as drama theory [30], decision conferencing [31], robustness analysis [32], and viable systems model [33]. Each of these has extensive experience “in the field” as well as being supported by a considerable body of theoretical and conceptual frameworks. More recently group model building ([34, 35]) has also been identified as a contender. Good compendiums of PSM theory

and practice can be found in Rosenhead and Mingers [16] and Reynolds and Holwell [36].

PSMs allow the capture and structuring of perceptions often times through graphical representations, for example, through causal maps in the case of SODA or rich pictures when using SSM. Moreover, they explicitly encourage the surfacing of socio-political considerations weaving in stakeholder management issues, conflict, competing priorities so as to provide a strong basis from which to negotiate a way forward. Each of the methods aims to ensure that different objectives/goals/aims are revealed, different options elicited and the means for their assessment identified once a good understanding of the situation has been gained. The captured material is explored with the group, using the various modeling techniques/analyses to foster the development of an enhanced understanding by participants, to enable a shared language to be developed, and through using the representation(s) to act as transitional objects [37] helping a group negotiate toward a set of improvements and actions to resolve the situation [23]. Models can also be considered boundary objects [38]

Alongside the development of PSMs, Jackson and Keys [39] taking a systems perspective, derived SOSM—system of systems methodologies—which helped to determine which types of problem were best resolved using a PSM/soft OR type approach. Problems with a high degree of complexity in terms of problem context and in terms of a wide range of relationships with stakeholders were considered prime candidates.

However, unfortunately while there is a body of literature expounding the methods in terms of underlying theories, guidelines for use and cases illustrating their application, these are not always appreciated and considered in a rigorous manner. Probably due to their subjective, qualitative nature, there are many reported instances where researchers and practitioners have asserted that they have used a particular soft OR approach but on closer scrutiny the application is poorly designed showing little evidence of a subtle and robust understanding of the methods in

terms of theory and practice thus tarnishing the method's reputation. This is a point noted by both White [40] and Ackermann [23]. These are not applications of soft OR.

WHY TEACH SOFT OR?

Williams [4] argues for five reasons for why PSMs/Soft OR should be used and therefore by implication taught (the reasons themselves are expounded in his MS textbook). These are where problems have

- (a) Multiple actors rather than a single one,
- (b) A reality that cannot be objectively determined,
- (c) Actors who have different aims, different objectives, and often different values,
- (d) Dynamic complexity that can be ill-understood and,
- (e) Behavioral complexity—many actors interacting in complex behavioral ways with underlying power-structures organizational politics and social geographies.

William's reasons for using PSM's recognize that there are different types of problems, those that are difficult but bounded (there is an agreed scope of work) and those that are messy and complex (reflecting the above criteria). These sorts of problems are likely to be faced by OR students in their day-to-day professional life. Traditional approaches to OR are geared toward tackling the former rather than the latter and thus are "necessarily confined to one corner of the field of organizational decision making" ([16], p. 8) recognizing that extending student repertoire is necessary. Moreover, problems that demand acknowledgment of soft human factors increasingly are taking up managerial time. Consequently, it is important to widen the scope of methodological support so OR's have methods for managing the "soft" messy problems and those that are difficult but more bounded. As noted later, however, providing students with the ability and confidence to manage these types of problems is itself a challenge particularly those

without organizational experience namely, undergraduates.

In addition, as noted in Rosenhead and Mingers [16], there is an aphorism from one of the earliest classics of the OR literature [41] stating "there is an old saying that a problem well put is half solved. This much is obvious. What is not so obvious is how to put a problem well." This is echoed by Einstein's observation that paying attention to the formulation of the problem is often the most important part of solving any problem. PSMs provide powerful mechanisms for determining which problem is to be considered, what it constitutes and getting agreement for this. This is clearly reflected in SSM where one of the first stages is to begin to get an understanding of the situation under consideration through the creation of a rich picture recognizing the need to be explicit. Similarly, SODA in the generation of causal maps encourages participants to surface the issues they are concerned with along with their implications allowing for an understanding of the whole to be gained before agreeing where to focus energy. Both these are examples of Goffman's [42] notion of framing where framing is concerned with how we make sense of events through employing a scheme of interpretation.

Another reason for providing students with an understanding of soft OR methods, is that in many situations, there are "participants for whom backroom analytic modeling would have been mystifying and excluding" ([16], p. 9). Appreciating the context is, if not mandatory for many applications of more quantitative methods, certainly important. Frequently OR students experience great disquiet when their beautifully executed piece of analysis is not adopted—not understanding that either it isn't really addressing the problem being experienced by the organization, or it doesn't consider the political landscape. Finding ways to engage decision makers and encourage them to understand and agree how to move forward, and thus buy into the resultant outcomes can be achieved using soft OR methods as a means of gaining agreement for the analysis, and helping with the management of the politics.

As such, soft OR is particularly relevant for working in the strategic strata

of problems where there is no clear single answer, and where there are multiple uncertainties. It is not surprising that SODA has evolved into an approach for making strategy, Strategic Choice was adopted into regional and city planning, and that system dynamics is used in policy analysis. Strategic decisions demand attention is spent on ensuring sustainable agreements are achieved as strategies usually require a long term view to be taken. This therefore requires decisions makers to recognize the need to attend to systemicity—that issues impact other issues, that options can have potency, and that some options are not feasible in terms of achieving particular outcomes. In essence, this is about recognizing the whole can be greater than the sum of the parts.

A final consideration for teaching soft OR is that while there are very few jobs explicitly requiring soft OR skills, virtually every decision that involves people requires knowledge of methods for managing both content and process and soft OR provides this.

WHO SHOULD BE TAUGHT?

The easy answer here is to argue for all students—as messy complex problems abound. However, when faced with the varying challenges experienced in designing curricula (itself a messy problem as there is not one single, right way to teach any subject or course!) students who are comfortable with working with people rather than in the backroom are likely to be more comfortable. This is because soft OR requires facilitation skills and acknowledges Langley's [43] view that "formal analysis and social interactive processes in organizations must be viewed as being closely intertwined rather than as mutually incompatible." Soft OR methods, as noted above, help support both process management and content management.

Another tranche of students who are prime candidates are those aspiring to be, or who already are, working in consultancy as providing them with the means to determine a good understanding of the situation can be very beneficial. As such Masters in Business Analytics courses, Masters in Business Management, or Management Science (MS)

would find learning about different soft OR methods useful. This is particularly the case for MS students who would be able to not only use the soft OR methods on their own but also combine them with the hard/quantitative methods allowing for the ability to tackle a very wide range of problems and thus increasing the chance of good job opportunities.

A further cohort for consideration is engineering students. This suggestion is based on observations that many of the progenitors of the soft OR methods came from an engineering discipline (e.g., Colin Eden and the development of SODA and Peter Checkland and the development of SSM) and thus it can be postulated that it was a lack in methods for supporting engineering projects that drove them to develop the methods thus rendering these methods apposite for those with aspiration of working in engineering jobs. In addition to this, is the fact that many of the case studies reported to have benefited from the use of soft OR are based in engineering firms (or those with engineering components e.g., Shell). Organizations which routinely take on board large projects involving a plethora of different organizational contributions (both intra and inter organizational), bespoke and potentially state of the art activities, and with tight time scales clearly will benefit from use of soft OR methods as gaining an understanding of the objectives, issues, and contributions in a systemic manner will help ensure successful conclusions.

Finally, staff working, or aiming to work, in public sector organizations would benefit from being skilled in soft OR. This assertion is based on a series of characteristics of public sector working. In the public sector, a wealth of stakeholders exists and thus the need to navigate a frequently politically fraught space is mandatory. There is rarely one agreed view on how the particular public mandate should be achieved, and seldom sufficient resources. Furthermore, public sector organizations are often at the mercy of the political direction which can experience sudden and drastic shifts. Thus, it becomes necessary to be able to make adjustments to the course of action in a sensible, shared, and sustainable manner. PSMs thus are

ideally suited to these sorts of characteristics that frequently manifest in the public sector. Consequently, teaching PSMs to students attending Masters of Public Administration courses or in-house programs will clearly have benefit.

WHEN TO TEACH SOFT OR?

From personal experience, the most fruitful tranche of students to teach soft OR methods to are those students who have experience in the “real” world and thus are able to appreciate the need to pay attention to issues relating to power, politics, and personalities. As such, Master’s course students rather than undergraduate students are the ones most likely to benefit from the exposure to PSM’s. This is not to say undergraduates won’t benefit. There are enough examples of undergraduates particularly those in their honors year for whom the methods really resonate and thus the students absorb the methods and become extremely proficient. However, in an undergraduate course such students are smaller in number than is normally the case for master’s students—and particularly MBA master’s students. This is partly because MBA students are post-experience and therefore will already be sensitized to the difficulties of getting agreement and action, particularly when instigating major change. Moreover, there will be an appreciation that politics do affect decision making, that there is rarely a single right answer and that negotiation is a key aspect.

Teaching soft OR at the beginning of a course also has been found to be advantageous. This is because students are able to use the methods during the course and after. For example, students have found being able to structure the content and manage processes (particularly when doing group assignments which proliferate in many courses) helpful in completing course work. Being able to pull together the key issues and understand how they fit together to form the whole can also help with studying as it can help holistic learners get a good overview and provide an effective means of ensuring successful outcomes. This is similar to the benefits gained from using Buzan’s mind maps [44]

which have an established pedigree in teaching and learning. The other benefit students can gain is from using the structuring techniques in the design, and in some cases execution of their final project, which for many master’s students is based in organizations where issues such as multiple conflicting views and uncertainty can be encountered.

The last aspect of “when” to teach soft OR relates to those teaching the techniques. Junior academic staff with little or no experience of industry, and whose doctoral studies are significantly desk based, are likely to find teaching soft OR a challenge. This is because a key element of soft OR is familiarity of organizational behavior. Junior staff are unlikely to have a repertoire of organizational problems that they have encountered and successfully managed and thus are limited when seeking to illustrate the application of soft OR methods as well as authentically expound the rationale for considering such techniques. Senior academics, on the other hand, who have worked with industry on projects, or who have extensive experience of University management are far more likely to be able to effectively present the need to attend to the socio-political considerations. Likewise those who have completed extensively quantitative degrees (honors or doctoral) may find teaching soft OR challenging. This is because their natural preference is for the very objective, quantitative world where there is little sympathy or natural affinity for human factor considerations.

HOW TO TEACH SOFT OR?

Teaching soft OR, however, is not easy even if you have experience in organizations. To begin with there are multiple challenges ranging from (i) difficulties in helping students appreciate the implications of the socio-political world, (ii) giving students confidence in not having the “right” answer, (iii) having to teach facilitation as well as the methods, (iv) providing students with an appreciation of the whole AND the details, (v) helping students manage complexity, uncertainty and holism, (vi) covering the material necessary within the time allocated to (vii) teaching the class on line [45].

However, there are, as noted in Ackermann's [45] paper, a number of means of managing these challenges and by being aware of the challenges and their management options, many difficulties can either be alleviated or avoided.

In addition, to support the teaching of soft OR, there is a growing body of scripts emerging [34, 46, 47] where workshop design is broken into "chunks" each chunk typically lasting 20 min providing a "product" (progress step) with the entire script resulting in a clear deliverable (helping resolve the situation at hand). Augmenting this research into scripts is the development of ThinkLets [48] whereby particular workshop designs are developed between an organization and an experienced facilitator with the intention that the designs are used in house on a regular basis. This unlocking of the black box of workshops [49] goes some way to resolving the issue of transferability recognized as early as 2006 [50].

When teaching the methods, the question of whether or not a good facilitator requires subject matter/substance knowledge is also pertinent [51]. Clearly, it is important to ensure that the facilitator avoids introducing bias into the meeting or confusing their role with the roles of participants but in many instances having some knowledge of the area, particularly some of the idiom and abbreviations can prove very helpful. Thus, familiarity with soft OR doesn't only demand good modeling skills but also process management and subject matter knowledge. This is very different from hard OR which is essentially practitioner free [52].

One of the challenges is what to teach. Given the finite amount of time available and the need to teach both content management (modeling) and process management, one of the questions is whether to focus on one or two methods allowing for competences in associated techniques to be acquired or to cover a wider range but at a relatively superficial level—allowing for a good overall understanding of the range but little actual practice. This decision needs to be considered alongside the objectives of the entire the course, and the quality/experience of the enrolled students. Moreover, based on

years of teaching PSMs, starting small and providing students with exercises and activities that allow them to gain familiarity and thus comfort is best. Providing case studies (see [53]) can help, so too, where possible, encouraging groups to try out the techniques in low risk environments, for example, helping a local group think about how to grow the local soccer team also helps in gaining confidence as well as competence.

It is also worth helping students recognize the very real possibility of change/adaptation being required and being comfortable to think of their feet. This is where understanding the theory helps as it provides a foundation upon which to adapt. Reflecting after interventions can also assist with the learning process. Students benefit from being alerted also to client management matters. For example, helping students understand the dynamic nature of problems and moving objectives [54].

While an ideal way of learning PSMs is through apprenticeship, this is an extremely costly method. However, if those mentoring and those receiving the mentoring begin to note some of the more tacit insights gained from working in a partnership then these can be fed into the scripts enriching the scripts and helping to ensure wider access.

CONCLUSIONS

As evidenced from the above, focusing on teaching soft OR from the perspective of the "5 wise men" shows that they are not mutually exclusive nor discrete as it is hard to separate the who from the when, the why from the how. Thus, all have to be considered alongside one another when considering teaching soft OR. Moreover, taking cognisance of the growing benefits and traction elicited from research and practice in mixing methodologies the fusion of soft and hard OR requires attention alerting students to the pitfalls but also benefits and means of method integration.

One very particular reason for teaching soft OR is its longevity. There are real concerns for its future based on the fact that many of the progenitors are retiring and leaving the field and thus there is a need to teach the methods so that they move into the

future. Traditionally as intimated above, the field of PSMs was dominated by a UK orientation with little development of the field taking place in OR/MS groups in the United States and beyond. However, when taking a wider view, that is, one beyond the OR/MS world, evidence of problem structuring like methods appear in the United States. For example, in policy where system dynamics is used to support groups working on complex policy issues and in the group decision and negotiation field. There is also evidence in the strategy arena for the value of soft OR principles—as authors have noted that when working with complex strategic problems, actions needed to be robust, owned, and relatively quick [18]. Seeking to integrate developments from these fields into the OR/MS world will help not only widen their accessibility but provide new stimulus for their development.

There is no doubt that any field of research needs continuous development and soft OR is no exception. For example, the methods would benefit from considering new developments in technology. One particular ICT avenue that offers real potential is advances in visualization. Firstly, because using some of breakthroughs in virtual reality give rise to opportunities for training environments where students can facilitate in a virtual world experiencing many of the likely behaviors in a risk free environment. Not only will technical competence be gained but also, on review of the virtual facilitation, reflections on how best to manage the process aspects is also possible. Another avenue for using visualization is the ability to move from modeling qualitative data on two dimensions to using three and gaining even more insights into emergent structure. New forms of analysis can thus be constructed giving decision makers even more assistance in making good decisions.

As noted by Vidal in an introduction to a special issue on PSMs “from an epistemological viewpoint we can stipulate that these (PSM) methods try to combine practical experience with theoretical knowledge, and objective facts with subjective appreciation with the purpose of problem solving in very complex situations” ([55], p. 529). Thus, they meet the twin requirements of rigor

and relevance. To conclude—in returning to the title of this article—Teaching Soft OR Methodologies: What, Why and How—the answer is because there is an overwhelming need for decision makers to either have access to those who can help them navigate messy complex situations or manage them themselves. Complexity is here to stay.

THE ANALYTICS SOCIETY OF IRELAND

CATHAL M. BRUGHA
Centre for Business
Analytics, School of
Business, University
College Dublin,
Belfield, Dublin 4,
Ireland

ESTABLISHMENT OF THE SOCIETY

The Analytics Society of Ireland (An Cumann Eireannach d'Anailísí in the Irish language) was founded in 1964 as the Operations Research Society of Ireland (ORSI). In 1985, the phrase *management science* was included in the name of the society, making it the Operations Research and Management Science Society of Ireland (ORMSSI). Subsequently, the society was extended to include Systems Science and Decision Science, and the name was changed to the Management Science Society of Ireland (MSSI). The society was known by this name until 2011, when the society recast itself as the Analytics Society of Ireland to reflect its members' perception that their work now primarily deals with analytics.

In 1972, the ORSI hosted one of the first IFORS conferences to be held in Europe. At this conference, the important decision to establish the Association of European Operational Research Societies (or EURO) was made. Over the years, the society has published newsletters and held annual conferences and student conferences. While the demand for national conferences and written newsletters in Ireland has declined in recent years, the society was at its most active from the mid-1960s to the mid-1980s and followed the pattern of the UK Operational Research Society. It was led by a small but enthusiastic group who were employed primarily in private industry. This group

included Dr. Fred Ridgeway (banking), Dr. Roy Johnston (consulting), Dr. Frank Bannister (who later joined TCD), and others. There were operations research (OR) units in the public service, Aer Lingus (airline), and Guinness (beverage industry). Many other applications, such as rural milk collection, were also implemented in Ireland. A member of the society, Professor Harry Harrison, was an early winner of the Edelman Award for his application in pharmaceutical distribution.

EVOLUTION OF OR IN IRELAND

By the mid-1990s, most OR units in Irish companies had disappeared, with the exception of Aer Lingus, which was eventually amalgamated into business strategy and now has reappeared as revenue management. Despite this trend, the practice of OR has increased and continues to grow but is now not seen by the Irish as a separate entity but rather as a function to be executed by people in engineering, finance, software, and information and communication technologies (ICT) (growth sectors in which the Irish export-orientated economy has strong links to the US industry).

For many years, the emphasis of the society was on organizing approximately a dozen seminars annually and providing an Internet-based link to members and interested people. Society members generally prefer international conference over national conferences, but they occasionally want to give papers at seminars in Ireland to spread the word on what they are doing and to have a dry run before presenting their work at international conferences. This reflects a change in the nature of the communication and culture of the society's members. Communication is now more immediate because of the availability of e-mail and is more international because of the Internet and the wide selection of specialist and general conferences. This also reflects a change in the orientation of members toward a

“small world” perspective. The proportion of members and former members who consider themselves to be OR specialists has declined over time, and the field has become more segmented and possibly also fragmented. Members of the society can be found working in decision support systems (DSS), expert systems, geographic DSS, decision science, soft OR, systems in general, case-based reasoning, information systems, information technology management, computer science, multicriteria decision making, data mining, environmental planning, multicriteria decision making, and so on.

This phenomenon is now reflected in the Analytics Society’s approach. Several years ago, the society carried out surveys of members, and as a consequence, formulated a new strategy for the society. The survey results showed that members did not find merit or value in attending meetings because of the pressures of time, work, and travel. Many of the applications practitioners are working on are quite advanced and specialized, and these practitioners find that their efforts overlap little with the work of others.

The society has built on this role as the key (driving) node of a network, linking alumni of the MSc and practitioners through its participation in IFORS, EURO, and OR Society conferences. The society has recently extended these efforts to conferences in related areas such as systems science [International Society for the Systems Sciences (ISSS), The International Federation for Systems Research (IFSR), etc.]. When society meetings were conducted, they focused on providing a forum for members to test their ideas before presenting them at international conferences. The Analytics Society now sees

itself as a support group for early career OR practitioners and academics.

RECENT HISTORY OF THE SOCIETY

Since 1991, the office of president has been held by Professor Cathal Brugha, who is the Director of the UCD Centre for Business Analytics in the School of Business at UCD. The Secretary since 1995 has been Dr. Joseph Coughlan, who is the Head of School of Accounting and Finance in the Dublin Institute of Technology.

Having joined UCD in 1991, Cathal Brugha took over the role of president and linked it to the MSc in Operations Research/Management Science in UCD (MMS) in UCD’s Smurfit Business School. Many of the officers of the society were alumni of this MSc, including Dave Darcy, David Doody, Pidge Lynch, and later Joe Coughlan. Recently the UCD Centre for Business Analytics has played a more active role, with Sean McGarraghy dealing with international affairs, and Peter Keenan with membership.

Since 1991, the society has had a continual representation at IFORS and EURO conferences and has participated in the annual council meetings of both groups. Brugha also served as the Editor of International Transactions in Operational Research (ITOR), the Official Journal of IFORS, from 2000 to 2006.

In the future, the Analytics Society of Ireland hopes to strengthen its links with private industry, serve as an alumni network, and provide opportunities for sharing and collaboration between business, academic institutions, and the state.

THE ASSOCIATION OF ASIA PACIFIC OPERATIONAL RESEARCH SOCIETIES

YAXIANG YUAN
DEGANG LIU
Academy of Mathematics and
Systems Science, Chinese
Academy of Sciences, Beijing,
China

The Association of Asia Pacific Operational Research Societies, abbreviated as APORS, is one of the regional groupings under the International Federation of Operational Research Societies (IFORS). Its objectives are to develop operational research (OR) as a unified science and advance it in the Asia-Pacific (AP) nations through sponsoring international meetings, exchanging information on OR, encouraging AP nations to establish their national societies, and promoting OR education and applications. By 2011, APORS has 12 member societies and becomes actively involved in all IFORS activities.

ESTABLISHMENT OF APORS

In 1984 during the tenth IFORS meeting in Washington, Prof. Masao Iri, the then IFORS Vice President, called a meeting of AP OR society representatives to discuss on possible launching of a society group in AP region. Through effective communication among these societies, a formal discussion was later called in March 1985 during the Operations Research Society of Japan (ORSJ) national meeting in Tsukuba, Japan on preparing the APORS, attended by IFORS national society representatives of Japan, China, Australia, New Zealand, Korea, India, Singapore, and Hong Kong. This meeting announced the APORS with mission of encouraging OR society exchanges in the region. A council composing representatives was established. Prof. Woong Bae Rha (Korea) was elected as the first APORS president, Prof. Guang-Hui Hsu (China) as vice president, Prof. K. Wakayama (Japan) as secretary, and

Prof. R. Johnston (Australia) as treasurer. It was also decided that the *Asia-Pacific Journal of Operational Research* (APJOR) edited by Singapore OR Society be published as APORS official journal and the first APORS meeting would be convened in Seoul in 1988. This first council meeting was hosted by the OR society of Japan. Its then president J. Kondo, representative H. Takamori, and Prof. M. Fushimi and Prof. K. Yanai from ORSJ also attended the launch meeting.

In August 1988 in Seoul, the Korea OR Society hosted the first APORS conference. Before the conference opened, an APORS council meeting was called. Prof. Guang-Hui Hsu (China) was elected as the second term president, Teresa Ling (Hong Kong) as vice president, and Prof. Wakayama continued his service as secretary. It was proposed that the second APORS meeting be convened in Beijing. During this term, Malaysia and Philippines OR societies joined the APORS.

In August 1991, OR society of China hosted the second triennial APORS conference in Beijing. Regular triennial APORS meetings have been hosted by Japan, Australia, Singapore, India, and Philippine OR societies. In 2009, India became again the host society of APORS conference in Jaipur, Rajasthan. In 2010, Malaysia hosted a between-triennial meeting in the city of Penang. China is going to host the ninth APORS meeting in Xi'an. APORS2015 is now in calling for proposals.

With two new members of Iran and Nepal OR societies having joined in 2008 and 2011, APORS now has 12 member societies and become one of the active regional groupings within the IFORS. Information sharing and exchanges within APORS have been increasingly strengthened to promote OR development in its members and outreach within IFORS.

MEMBER SOCIETIES

As APORS is a regional grouping of OR societies within IFORS, member societies of

AP regions will automatically become part of APORS. By the end of 2011, APORS consisted of 12 member societies: Australia (ASOR), China (ORSC), Hong Kong (ORSHK), India (ORSI), Iran (IORS), Japan (ORSJ), Korea (KORMS), Malaysia (MSORMS), Nepal (ORSN), New Zealand (ORSNZ), Philippines (ORSP), and Singapore (ORSS).

The *Australia Society for Operational Research (ASOR)* (<http://www.asor.org.au>) was founded on January 1, 1972, and has about 400 members nationwide. ASOR serves the professional needs of OR analysts, managers, students, and educators by publishing a National Bulletin and National and Chapter Newsletters. The society also serves as a focal point for operations researchers to communicate with each other and to reach out to other professional societies. The current term ASOR President is Prof. Baikunth Nath of the University of Melbourne. ASOR is composed of six branches or chapters in the nation's states, which organize their activities. Every two years, ASOR calls a national conference. As founding member of APORS, ASOR hosted the fourth APORS meeting in Melbourne in 1997. In 2011, the society successfully hosted IFORS triennial conference at the same city with more than 1200 participants. This is the first IFORS meeting in the Oceanic. An academic journal *ASOR Bulletin* is published in four issues every year.

The *Operations Research Society of China (ORSC)* (<http://www.orsc.org.cn>) was founded in 1980 and became a member of IFORS in 1982. Now ORSC has more than 1200 registered members and around 500 are active. The current president is Prof. Yaxiang Yuan who is also the current APORS president. Within ORSC, 13 special interesting groups have been set up, for example, Mathematical Programming, Queuing Theory, Reliability, Decision Science, Uncertainty Systems, Intelligence Computing, Scheduling, Graph Theories & Combinatorics, Fuzzy Optimization, Game Theory, Financial Engineering, and recently the Computational System Biology. These technical groups meet once or every other year, apart from national society meeting once every other year, for a national conference or international conference.

ORSC has two official journals: *OR Transactions*, a quarterly journal (Prof. Yaxiang Yuan as Editor-in-Chief), that publishes original theoretical articles and *OR and MS*, a bimonthly journal (Edited-in-Chief by Prof. Xiang-Sun Zhang) that aims at both theoretical research and innovative application. Traditionally, every four years, ORSC will have a National Congress supplemented by a biannual academic conference. The most recent quadrennial meeting was held in 2008 attended by over 450 participants. The Congress featured plenary talks, paper presentations, the ORSC election, several prize competition, and committee meetings.

The *Operations Research Society of Hong Kong (ORSHK)* joined IFORS in 1980 with 120 members. The current President is Prof. Yan Chong Chen. As an active APORS member society, ORSHK work closely with universities and industries in Hong Kong to encourage operational research applications in areas such as logistics, shipping, manufacturing, and management. ORSHK has not created its web site.

The *Operational Research Society of India (ORSI)* (<http://www.orsi.in>) was founded in 1957 to provide a forum for the Operational Research Scientists as well as an avenue to widen their horizon by exchange of knowledge and application of techniques from outside the country. At present, the Society has 10 operating chapters located in Agra, Ahmedabad, Bangalore, Chennai, Delhi, Durgapur, Jamshedpur, Kolkata, Mumbai, and Tirupati.

The Society publishes a quarterly journal *OPSEARCH*, which brings out high quality and state-of-the-art papers in OR. The journal enjoys a wide spectrum of readership in both the India and abroad, covering academics, professionals, as well as industrial/service sector organizations. ORSI is conducting an examination on Graduate Diploma in Operational Research since 1973.

The *Iranian Operations Research Society (IORS)* (<http://www.iors.ir>) was established in 2005 and became the fiftieth national member of IFORS on December 16, 2009. Currently, the Society is managed by its second Executive Council to be replaced by the third Executive Council in May

2010 (the term for the council is three years). IORS currently has 134 members, mostly composed of college scholars and industry professionals. The scholars are mostly drawn from Mathematics, Industrial Engineering, and Management Sciences departments.

IORs publishes the international scientific journal, *Iranian Journal of Operations Research* (IJOR). The publication is semianual and was first published in 2009. IORS also organizes the annual International Conference of Iranian Operations Research Society. The latest International Conference of Iranian Operations Research Society on May 5–6, 2010, at the Amirkabir University of Technology, Tehran, in which ~200 were selected for oral presentations and 100 were selected as posters.

The *Operations Research Society of Japan* (ORSJ) (<http://www.orsj.or.jp>) was established on June 15, 1957. In addition to such pursuits as research on OR theory and the development of methodologies, the ORSJ explores the practical use of methods applicable to specific problems occurring in the world of business and government offices. It also actively promotes exchanges of information among its members as well as interaction on an international level. Headquartered in Tokyo, ORSJ has six chapters around the country. Each regional chapter conducts its own slate of activities, including lectures and research projects. Now ORSJ has over 2000 regular members and 170 student members, as well as 60 corporate members. *Journal of the Operations Research Society of Japan* (JORSJ) is a professional journal in Japanese language issued four times a year. From 2010, JORSJ are freely accessible at ORSJ webpage <http://www.orsj.or.jp/~archive/>. ORSJ organized two national meetings each year in spring at Tokyo and fall in elsewhere in Japan.

The *Korean Operations Research and Management Science Society* (KORMS), (<http://www.korms.or.kr>) established in June 1977 under the jurisdiction of the Ministry of Science and Technology, is a professional organization in Korea for individuals and organizations interested in the fields of OR or

Management Science (MS). KORMS has six special interest groups (SIGs). The activities of each SIG include holding international and domestic conferences; running various seminars, and publishing newsletters and proceedings. The SIGs are on Management Information Systems, Information Technology, Networks, Industrial Applications of Geographic Information Systems, Data Mining, and Material Handling System for New Millennium. The society also has several branches to promote regional cohesion and to maintain a balance of activities around the nation.

The Society publishes two journals and a review. The *Journal*, which publishes new and innovative research results, is published in two categories. *Journal* (A) is published four times a year, while *Journal* (B) is published in English twice a year and focuses on theoretical issues. The *Review* is a biannual publication that covers applied research, surveys, and articles on MS/OR trends.

KORMS holds conferences twice a year. The Fall Conference is held in the Seoul metropolitan area, while the Spring meeting convenes in other areas of the country. The conference programs include technical sessions, invited lectures, and tutorials. General assembly meetings are also held during the conferences; these comprise both regular and special sessions.

The *Management Science/Operations Research Society of Malaysia* (MSORSRM) (<http://www.msorsrm.org>) was registered as a professional society in July 1986. MSORSRM is the thirty-sixth national member of the IFORS, ninth national member of the APORS, and member of the Confederation of Scientific and Technological Association in Malaysia (COSTAM). MSORSRM offers five types of membership, that is, ordinary member, student member, corporate member, life member, and fellow. MSORSRM is currently planning for APORS triennial conference in 2015 in Kuching Sarawak, Malaysia.

The *Operational Research Society of Nepal* (ORSN) (<http://orsn.org.np/>) is founded in 2007 to capitalize its applicability in the related fields and also to develop a common platform extensively for the MS professionals. ORSN officially joined IFORS and hence

APORS in November 2011 and become the youngest member society of the association. In February 2012, ORSN held its first international conference in Kathmandu, Nepal, in which ORSN invited IFORS immediate past president, chair of the IFORS OR for Development Committee, and several internationally prominent professors from INFORMS. ORSN focuses OR methodologies and applications in the practical topics of sustained development, such as in financing, marketing, tourism, healthcare, among others.

The *Operational Research Society of New Zealand (ORSNZ)* (<http://www.orsnz.org.nz>) was founded in 1965 as a nationwide not-for-profit body comprising academics and public servants, consultants, and practitioners in industry. It currently has over 150 members within New Zealand and is affiliated to APORS, IFORS, and the Royal Society of New Zealand. The primary aim of the Society is to promote OR and MS in New Zealand to industrial and academic groups. The Society publishes a regular newsletter; organizes branch meetings in Auckland, Wellington, and Christchurch; and runs an annual two-day conference in late November/early December, with the conference location shifting between the University of Auckland, the University of Canterbury in Christchurch, and the University of Victoria in Wellington.

The *Operational Research Society of Philippines (ORSP)* (<http://www.orsp.org.ph/>) was launched in 1987 and held the first ORSP symposium in June. In December 1990, the ORSP went international and hosted its first International Conference on OR/MS (ICORMS). At about the same time, the first issue of the *Philippine Journal of Operations Research* was published. In 1997, ORSP hosted the second ICORMS, conducted jointly with the IFORS' annual International Conference on OR in Development (ICORD). Another international event, the IFORS Workshop for Teachers in Developing Countries, was successfully organized by ORSP in July 2004. In 2006, ORSP played host for the first time to the APORS) Seventh Conference. ORSP owns regular, honorary, and institutional members.

The *Operational Research Society of Singapore (ORSS)* was officially registered in November 1975. The founding president of ORSS, Professor Chew Kim Lin, is also thus far the longest serving president. The ORSS was subsequently admitted as a full member of the IFORS in 1978. ORSS is also a founding member society of APORS in 1984. It grew to a size of about more than 100 members in the late 1980s. Since then, it has maintained this number of members, though, with increasing proportion of life members. The individual members come from the academia, government agencies, and industry. A fair number of its life members are in the defense (military) and national security organizations. One of the objectives for ORSS is to promote the practical use of OR in industry, commerce, and public administration.

RUNNING THE APORS, JOURNALS, AND AFFILIATED ORGANIZATIONS

APORS, like other regional groupings within IFORS, does not support a secretariat for daily operation. Instead, its president and his/her national society provide secretariat function in communicating with other member societies. So far, APORS does not have any funding source. Therefore, the council meeting, generally during APORS and IFORS conferences, plays critical part in discussing some important matters and making decisions on election, triennial conference host, collaborative activities, and so on.

APORS officers are elected once every three years during the APORS triennial conference. The executive committee includes president, vice president, secretary, treasurer, and a representative to IFORS as IFORS Vice President for APORS. The past and current term APORS presidents are

- 1986–1988, Woong Bae Rha (Korea)
- 1989–1991, Guang-Hui Hsu (China)
- 1992–1994, Masao Iri (Japan)
- 1995–1997, Santosh Kumar (Australia)

1998–2000, Kim Lin Chew (Singapore)
 2001–2003, S.P. Mukherjee (India)
 2004–2006, Elise A. del Rosario (Philippines)
 2007–2009, Chun Kwong Han (Malaysia)
 2010–2012, Yaxiang Yuan (China)
 2013–2015, Illias Mamat (Malaysia).

APORS publishes a bimonthly journal *JAPOR (Journal of Asia-Pacific Operational Research)*, <http://www.worldscientific.com/worldscinet/apjor>. The journal places submissions in general, theoretical, OR practice, reviewer survey, OR education, and communications including short articles and letters. Emphasis is on originality, quality, and importance, with particular emphasis given to the practical significance of the results. Practical papers, illustrating the application of OR, are of special interest. Being recognized as an official publication of APORS, the journal is edited, managed, and published by ORSS in Singapore.

The ORSS started publishing the inaugural volume of *Asia-Pacific Journal of Operational Research (APJOR)* in 1984, and this was subsequently adopted as the official journal of the APORS. APJOR provides a forum for practitioners, academics, and researchers in OR and related fields, within and beyond the AP region. It is currently published by the World Scientific Publishing Co., and the ORSS continues to play an active management role in running this journal.

To promote the cooperation with OR colleagues in the AP area and the rest of the world, the Asia-Pacific Operations Research Center (APORC) was set up in 1995 in Beijing. The center is affiliated with the Chinese Academy of Sciences (CAS) and APORS. Major activities of the APORC include receiving academic visitors from APORS members and organizing regional seminars and workshops.

ACTIVITIES

Since its founding, APORS organizes a regular triennial academic conference every three

years. The past APORS meetings, locations, and hosts are listed in the following table.

Year	Venue	Host/Chair
1988	Seoul, Korea	Woong Bae Rha
1991	Beijing, China	Guang-Hui Hsu
1994	Fukuoka, Japan	Masao Iri
1997	Melbourne, Australia	Santosh Kumar
2000	Singapore	Kim Lin Chew
2003	New Delhi, India	S.P. Mukherjee
2006	Manila, Philippines	Elise A. del Rosario
2009	Jaipur, India	Bani K. Sinha
2010	Penang, Malaysia	Illias Mamat
2012	Xi'an, China	Yaxiang Yuan
2015	Kuching, Malaysia	Illias Mamat

With support from APORS member societies, China and Australia hosted successfully the IFORS1999 in Beijing and IFORS2011 in Melbourne.

By 2011, APORC has organized 10 symposiums entitled “International Symposium on Operations Research and Applications in Engineering, Technology and Management (ISORA)” that attracts regular attendees from APORS member societies. One of the main features of ISORA is that the series meetings have been located in different cultural environment in virtue of the cultural diversity of China. The first ISORA was launched in Beijing in 1995 and then followed by nine symposiums held at different towns in China. Among these places, Lhasa in Tibet, Urumqi in Xinjiang, Lijiang in Yunnan, and Dunhuang in Gansu are the most attractive ethnic minority areas. The symposiums bring OR professionals to local people and universities and meanwhile giving participants an opportunity to enjoy the highlight of the local culture. ISORA proceedings are collected into the “Lecture

Notes in Operations Research” published locally by the World Publishing Corporation.

Looking forward, we believe that APORS will play an increasingly strong role in the

future in linking OR communities in the region and demonstrating OR best practices toward a sustainable world.

THE BULGARIAN OPERATIONAL RESEARCH SOCIETY

NICOLA YANEV
Faculty of Mathematics and
Informatics, University of
Sofia "St. Kl. Ohridski",
Sofia, Bulgaria

The Bulgarian Operational Research Society (BORS) was registered as a scientific not-for-profit association on November 2, 1992 and became a member of the International Federation of Operational Research Societies (IFORS) and the European Association of Operational Research Societies (EURO) in 1994. It is a self-sufficient juridical body formed as a union of its members, in accordance with the Law for Persons and Family. The seat of BORS is in Sofia, Bulgaria, in the Institute of Informatics (now the Institute of Information Technology) within the Bulgarian Academy of Sciences where the permanent Technical Secretariat is located.

The main objectives of BORS are

- to help and encourage the scientific and creative development of its members and contribute to their efficient participation in scientific and technical activities within the field of Operational Research (OR);
- to encourage initiatives and carry out activities by
 - contributing to the development of research and applications of OR in Bulgaria, and to the improvement of their prestige and authority of OR researchers;
 - fostering, in the broadest sense, training and education in OR;
 - collaborating on scientific, methodological, and organizational cooperation with international and national scientific conferences, schools, and

other scientific OR activities held in Bulgaria and abroad;

- contributing to the activities of the IFORS and the EURO.

BORS membership categories are as follows

- *Qualified Member*. This refers to any person who has at least three years of professional or scientific experience or two publications in international journals or proceedings in the field of OR or other relevant fields may apply for qualified membership.
- *Honorable Member*. This refers to persons who have made significant contributions to the development of OR or the promotion of BORS.
- *Collective Member*. This is a juridical person from the public and the private sector, enterprises, banks, and other organizations, interested in BORS objectives, and/or giving grants to BORS.
- *Student Member*. This consists of students in universities, who have studied OR subjects.

Members of the society are entitled to the following privileges:

- reduced fees for conferences, seminars, and courses organized by the society;
- discounted subscription rates to the society's publications;
- opportunity to meet fellow OR practitioners.

The number of qualified members in 1992 was 19, and has risen to 40; at present, BORS has approximately 20 members.

BORS participated/sponsored/assisted in organizing the following conferences/seminars/workshops:

- IV International Conference on Mathematical Methods in OR, Sozopol, September 1997;
- regular seminars in the OR section of the Institute of Mathematics and Informatics, Bulgarian Academy of Sciences;
- workshop on Well-Posedness in optimization and related topics, Sozopol, Borovets, September 2005.

The Presidents of BORS have been:

- 1992–1996: Peter Kenderov, academician in the Bulgarian Academy of Sciences;
- 1996–present: Nicola Yanev, Professor in Sofia University.

Founded in 1958 and incorporated on 25 February 1964, the Canadian Operational Research Society (CORS) takes a leadership role in the advancement of both the theory and practice of operational research (OR) in Canada, and it represents the Canadian OR community in the International Federation of Operational Research Societies (IFORS). We meet our objectives with our publications, Web site (www.cors.ca), and annual conference and by supporting a diverse array of local section activities. The society is bilingual and is also known as the Société canadienne de recherche opérationnelle (SCRO).

ORIGINS

In 1963, P. J. Sandiford [1] wrote on the origin and growth of CORS. That article gave a synopsis of the first five years of CORS history, and it appeared as the first article in the first issue of the Society's peer-reviewed journal, then called the *CORS Journal* and, since 1971, called *INFOR*. We present a brief

synopsis. In 1957, the only OR society in Canada was the Operations Research Society of Toronto. There was significant OR activity in both Montreal and Ottawa, and practitioners in those centers and elsewhere in Canada joined either ORSA (Operations Research Society of America) or TIMS (The Institute of Management Sciences), or both.

In 1957, IFORS was created, and the first secretary was a Canadian, Sir Charles Goodeve. Goodeve played a prominent role in the development of OR during wartime in Britain and was, at the time, the Director of the British Iron and Steel Research Association. In 1956, he was concerned that Canada would have no national society to join IFORS, and so he called on Dr. Omond Solandt, another significant Canadian figure of wartime OR in Britain, to try and form such a society. On 11 February 1958, representatives from Ottawa, Toronto, and Montreal met in Montreal and elected Solandt the provisional chair. The inaugural meeting of CORS was held in Toronto on 14 April 1958. Solandt was elected president. By the end of the first year, the Society had 161 members. The triangular CORS logo (Fig. 1) reflects the three founding OR centers in Canada (Ottawa, Toronto, and Montreal). Goodeve's desire for Canadian representation and membership in IFORS was realized on 1 July 1959.

CORS now has 403 members including 7 emeritus, 17 retired, and 106 student members. It is managed by a council composed of the president, vice president, secretary, treasurer, four councilors, immediate past president, designated representatives from each of the 13 local sections (including three student sections), and the chairs of the five standing committees. CORS is supported by a professional, part-time administrator.

PUBLICATIONS

The Society has two publications: a quarterly newsletter (*The CORS Bulletin*) and the peer-reviewed journal *INFOR*. *The Bulletin* is published in both English and French, and

Figure 1. Canadian Operational Research Society logo.

INFOR publishes articles in either English or French.

The peer-reviewed papers published in *INFOR* highlight recent advances in OR, and the journal contains many papers that combine theory and methodology with OR practice. The journal editors promise quick review of submissions. The first issue of the journal was published in December 1963 at which time it was called *The CORS Journal*. The first French article appeared in March 1968 [2]. In March 1971, the name of the journal was changed to *INFOR Journal* to reflect a partnership between CORS and the Canadian Information Processing Society (CIPS). In August 1985 (Vol. 23. No. 3), the name was shortened to the current *INFOR*. The relationship with CIPS ended with the publication in November 1999 of Vol. 37. No. 4. The journal is published quarterly and is distributed, either online or in print, to 121 institutions, 13 abstract and index companies, and 417 individuals in Canada and abroad.

The Bulletin provides information on conferences and awards, highlights member accomplishments, and publishes special articles highlighting OR activities across the country. It is a bilingual publication and is a membership benefit. The first issue was published in 1962, and it is now distributed electronically with separate French and English versions.

MEETINGS

The 1958 meeting that led to the establishment of CORS is considered its zeroth

meeting. The first meeting was in 1959 in Toronto and the meetings have since continued without interruption. The 53rd meeting was at St. John's Newfoundland in May 2011. In 1964, we hosted our first joint meeting, with ORSA as the partner. The success of this format led to future joint meetings with ORSA/TIMS, IFORS, Institute for Operations Research and the Management Sciences (INFORMS), and MITACS. A complete list of conferences can be found in [3].

AWARDS

The awards banquet is a feature of the annual meetings, and CORS has several prestigious prizes. Complete details, including recipients, can be found at www.cors.ca/prizes.

The Harold Larnder Prize is awarded annually to an individual who has achieved international distinction in OR. The winner delivers a keynote plenary address at the annual conference. Harold Larnder played a major role in the development of the radar-based air defense system and in the deployment of aircraft during the Battle of Britain [4]. He returned to Canada in 1951 to join the Defence Research Board and was the president of CORS in 1966–1967. The first winner of the Larnder prize was Eugene Woolsey (1986) and the most recent was John D. C. Little (2010).

The Omond Solandt Award is awarded to an organization, private or governmental, that is deemed to have made an outstanding contribution to OR in Canada. Dr. Solandt was the founder and first chairman of the Defence Research Board in Canada. He served as head of the Science Council of Canada, vice-chairman of the Canadian National Railways, and chancellor of the University of Toronto [5]. The first winner was Canada Packers (1978), and the most recent winner was Maplesoft at Waterloo, Ontario (2009).

The Award of Merit is awarded to a present or past member of CORS in recognition of significant contributions to the profession of OR. The first winner was Omond Solandt (1983), and the most recent winner was Bernard Gendron (2010).

The Service Awards recognize members of the Society who have made outstanding contributions of time and service.

COMPETITIONS

Each conference hosts a practice prize competition as well as a student paper competition. *The Practice Prize* is to recognize outstanding OR practice and to focus attention on the application of OR in Canada. The entries are judged by the impact on the client organization, contribution to the practice of OR, quality of analysis, degree of challenge, and quality of written and oral presentations. The most recent (2010) winners were Burcin Bozkaya, Erhan Erkut, Dan Haight, and Gilbert Laporte for their project entitled "Designing New Electoral Districts for the City of Edmonton."

The Student Paper Competition is to recognize the contribution of a paper either directly to the field of OR through the development of methodology or to another field through the application of OR. The competition showcases the high quality of OR education in Canada and the excellence of the next generation of operations researchers. The most recent winner (2010) in the open category was Ramon Alanis, School of Business, University of Alberta, for his paper, "A Markov Chain Model for the Performance of an EMS System with Repositioning." In the undergraduate category, the 2010 winners were Erin Hrycyszyn, Felicia Ng, Brent Ouwerkerk, Jimmie Tom, and Sean Tomilin, from the University of Alberta for the paper "Community Facility Services: Drive Time and Market Share Analysis."

THE CORS DIPLOMA

The CORS Diploma is awarded by CORS, in association with the participating Canadian universities, to recognize CORS members who have successfully completed a program of study that has included significant exposure to OR in the following areas: OR techniques, probability and statistics, computers and systems, and applications of OR. Over 900 diplomas have been given to students from over 25 Canadian universities.

THE WEB SITE

Much of the information in this article, and much more, can be found at www.cors.ca. This includes Refs 1, 3–5; complete lists of prize and award winners; past presidents; conference locations; and past issues of the Bulletin.

GENERAL INTRODUCTION

Today's products tend to have high reliability and can last for long periods of time. In general, doing reliability assessment and maintenance planning based only on failure-time data is difficult because these studies tend to yield few or no failures. System or component operating-condition information, however, can be obtained in a more timely manner than the corresponding failure-time information. Thus, the condition information plays an important role in reliability assessment and maintenance for many systems, especially for products or systems that require a high level of reliability or availability. The information from condition monitoring can be used for the assessment of short- and long-term reliability and scheduling of maintenance like repairs and replacements.

In practice, various system condition variables can be monitored through appropriate measurement techniques. These conditions include vibration of a system, particles and chemical elements that are released into the environment by a system, fatigue-crack sizes, temperature of a system, the resistance, conductivity of certain components, and so on. Moubray [1, Appendix 4] provides various

examples and information about existing technology used for condition monitoring. When the condition variable changes, system deterioration might be detected. Deterioration can happen in physical conditions, such as tire wear, chemical concentration, or the size of a fatigue crack. Deteriorations can also be detected in system performance such as the power output of an amplifier or the intensity of an LED. Both cases are referred to as *degradation*. Physical degradation or performance degradation can be measured as a function of time, depending on the application. These repeated measurements are generically referred to as *degradation data*. Degradation data may be available continuously or at specific time points where measurements were taken.

In many applications, there is a relationship between the system degradation and system failure. The condition information is used to obtain the reliability information. For example, when the size of a fatigue crack is increasing or the tire-tread depth is decreasing, a failure could be defined to occur when the degradation level crosses a certain threshold. Failures defined by a degradation level crossing a threshold, without complete loss of functionality, are often called *soft failures*. Failures that result in complete loss of functionality (but generally not corresponding exactly with a particular level of degradation) are called *hard failures* [2, Chapter 13]. The relationship between the amount of degradation and the failure time makes it possible to use degradation data and degradation models to make inferences and predictions about failure time. Degradation data, when properly collected and analyzed, can provide much more information than failure-time data because there are quantitative measurements on all units.

RELATED LITERATURE

During the last thirty years, there have been numerous reliability studies using

degradation data. Gertsbakh and Kordonsky [3] present and discuss some early ideas on the use of degradation models in reliability. Through the 1990s and continuing to the present, various statistical methods have been developed to get reliability information from degradation data. These methods are now beginning to be available in commercial statistical software. Murray [4] fits models to the sample paths for individual units and extrapolates the sample path until some failure level to obtain “pseudo failure” data. The “pseudo failures” are treated as failures and they are analyzed using the standard methodology available for failure-time data. Lu and Meeker [5], and Meeker *et al.* [6] use a random effects model to describe unit-to-unit variability and discuss the failure-time distribution induced by the degradation model. In some areas of application, it is useful to model the stochastic behavior in the sample paths. For this purpose, the Wiener process [7] and the Gamma process [8] are useful in stochastic modeling. Wang [9] gives a brief survey of physical degradation models.

EXAMPLES OF DEGRADATION DATA

Here, we give two examples of degradation data, which will be used to illustrate the

models in the section titled “Statistical Models and Methods for Degradation Data.”

Example 1 [Laser life data]. Figure 1 is a plot of the degradation data from 15 laser units [2, Example 13.10]. These devices, designed for telecommunication applications, have a feedback circuit to maintain constant light output. Current is increased over time to compensate for the degradation in the lasing material. The operating current was measured over time and the percentage increase in operating current was reported. For this application, a 10% increase in percentage was the specified failure level.

Example 2 [Outdoor weathering data]. Figure 2 shows damage to an epoxy compound as a function of the effective dosage for a subset of the specimens, as described in Vaca-Trigo and Meeker [10]. The damage to the compound is caused by the exposure to the outdoor ultraviolet radiation (i.e., photo-degradation). The damage was measured repeatedly after every few days of exposure and the effective dosage was also recorded. Effective dosage, which is a number that is proportional to the number of photons absorbed into the experimental specimens, is, scientifically, the appropriate timescale

Figure 1. Laser operating current.

Figure 2. Plot of the damage to an epoxy compound due to outdoor weathering for a subset of specimens. A unit with damage below the critical level of -0.45 is considered a failed unit with a failure time equal to the crossing time (the timescale here is the effective dosage).

for the degradation process. There was no control of some of experimental variables such as, temperature and humidity, but these variables were also measured carefully. The degradation paths generally show more variability than laboratory test data for similar studies. For purposes of illustration, we set the definition of failure at the damage level of -0.45 , shown as a horizontal line in Fig. 2. There was a total of 13 failures that resulted for this level of damage, out of the total 55 specimens (Fig. 2 shows only a subset of specimens with 4 failures).

STATISTICAL MODELS AND METHODS FOR DEGRADATION DATA

Relationship between Degradation and Failure Time

Let $\mathcal{D}(t)$ be the degradation level at time t . Depending on the nature of the degradation process, the degradation path can be a linear, convex, or concave function of time or the amount of usage (e.g., see Meeker and Escobar [2, p. 319] for more details). A soft failure occurs when the degradation level $\mathcal{D}(t)$ reaches the failure-definition level $\mathcal{D}_f$ at time T . The failure time of the unit is T . Figure 3

gives an illustration of the possible shapes of the degradation curves, and the relationship between the degradation levels and the soft failure times.

In general, the cumulative distribution function (cdf) of T , which gives the fraction of the population failing before time t , can be obtained by

$$F(t) = \Pr(T \leq t) = \Pr[\mathcal{D}(t) \geq \mathcal{D}_f],$$

if the degradation is increasing and there is a similar definition if the degradation is decreasing. The estimate of $F(t)$ can be obtained based on the observed degradation paths of the units. The assessment of risk of failure at a future time and the corresponding maintenance scheduling can be based on the estimates of $F(t)$.

Approximate Degradation Analysis

We begin with a simple method of analyzing degradation data that is commonly used by engineers. The first step of the approximate method is to find a transformation for the degradation and/or the time such that the transformed degradation path is approximately a linear function of transformed time. No transformation is needed if the paths are

Figure 3. Illustration of the relationship between the degradation level and the failure time.

already approximately linear. Then separate simple linear regression lines are fit for each unit to predict the time at which the unit will reach the specified failure-definition level D_f . These times are called *pseudo failure times*. These pseudo failure times are then analyzed with statistical methods for failure-time data to estimate $F(t)$. The method is called the *approximate method* because the analysis is based on these pseudo failure times. See Meeker and Escobar [2, Section 13.9] for more details about the approximate method.

For simple problems, the approximate degradation analysis method is attractive because the computations are relatively simple. The approximate method is less appealing, however, when the degradation paths cannot be transformed to be approximately linear. Meeker and Escobar [2, pp. 337–338] discuss conditions for which the approximate method is adequate and potential problems with the approximate method.

Example 3 [Laser life data analysis using the approximate method]. The data for this example are shown in Fig. 1. In this case, no transformation is needed because the original paths are already approximately linear. Failure is defined as the point in time when there is a 10%

increase in current. For those lasers that did not reach this level, pseudo failure times were obtained by fitting straight lines through the sample path of the laser. These pseudo failures are analyzed using the common failure-time analysis [2, Chapter 8].

Figure 4 is a Weibull probability plot of the laser pseudo failure times showing the ML estimate for $F(t)$ and pointwise approximate 95% confidence intervals. Figure 4 also shows the Kaplan-Meier [11] estimate of the failure-time cdf, which is a step (staircase) function of time that jumps at each failure time (t_i) by an amount that is determined by the number of units at risk at t_i , the number of failures at t_i , the number of units that have been censored prior to t_i , and the original number of units in the study. The dots at each failure time are plotted halfway up each step in the Kaplan-Meier estimate, as explained in Lawless [12, Section 3.3].

Random Effects Path Model

The random effects path model is a more general and sophisticated approach to analyze degradation data. The motivation for the random effects path model is that there is unit-to-unit variability in the degradation path, which may be caused by initial conditions, material properties, and component

Figure 4. Weibull probability plot for the laser pseudo failure times showing the ML estimate for $F(t)$ and the pointwise approximate 95% confidence intervals. The dots track the Kaplan–Meier estimate of the cdf $F(t)$.

dimensions. That is, individual units will vary with respect to the amount of material available to wear, the initial level of degradation, amount of harmful degradation-causing material, and so on. The rate of degradation for the individual may also depend on its operating and environmental conditions. Conditional on a unit's parameters and operating/environmental conditions, however, the degradation path for the unit is assumed to be deterministic (i.e., the degradation path is deterministic function of time). This kind of degradation model is sometimes referred to as a *deterministic model*.

In practice, the values of the degradation level, $\mathcal{D}(t)$, are observed or measured at discrete points in time. The observed degradation for unit i at time t_{ij} is

$$y_{ij} = \mathcal{D}_{ij} + \epsilon_{ij},$$

where $\mathcal{D}_{ij} = \mathcal{D}(t_{ij}, \beta_{1i}, \dots, \beta_{ki})$ and ϵ_{ij} are the actual path and the residual deviation for unit i at t_{ij} , respectively. Some of the $\beta_1, \dots, \beta_k$ could be random from unit to unit to account for the unit-to-unit variability. One or more of the $\beta_1, \dots, \beta_k$, however, could be modeled as common (fixed) across all units. When the times where the degradation

is measured are not too close together, a common and plausible assumption is that the ϵ_{ij} are independent and $\text{NOR}(0, \sigma_\epsilon)$ distributed, where σ_ϵ is the standard deviation of the distribution.

The underlying model parameters, denoted by θ , consist of the parameters that determine the distribution of the random effects plus the fixed parameters. θ can be estimated using the method of maximum likelihood with the computations implemented, for example, with the `lme` or `nlme` functions in S-PLUS or R. More information can be found in Meeker and Escobar [2, Section 13.3].

For the random effects path model, the cdf of the induced failure-time distribution is

$$F(t) = F(t; \theta) = \Pr(T \leq t) = \Pr[\mathcal{D}(t) \geq \mathcal{D}_f],$$

if the degradation is increasing (and there is a similar definition for decreasing degradation). In some simple cases, it is possible to write down the explicit form of $F(t)$. For most practical path models, especially when $\mathcal{D}(t)$ is nonlinear and more than one of the $\beta_{1i}, \dots, \beta_{ki}$ parameters is random, it is necessary to compute $F(t)$ using numerical methods. For example, Meeker

Figure 5. Degradation model estimate of $F(t)$ with pointwise approximate 90% confidence bootstrap intervals (CIs) for the outdoor weathering data, based on the random effects degradation model. The dots track the Kaplan–Meier estimate of the cdf $F(t)$.

and Escobar [2, Section 13.5] give algorithms to evaluate $F(t)$ via numerical integration and Monte Carlo simulation.

Example 4 [Linear degradation with a lognormal rate]. Here, we give a simple example where the $F(t)$ can be obtained explicitly. Suppose the actual path is

$$D(t) = \beta_1 + \beta_2 t,$$

where β_1 is fixed and β_2 has a lognormal distribution with parameters μ and σ . The cdf of T can be obtained explicitly as

$$\begin{aligned} F(t; \beta_1, \mu, \sigma) &= \Pr[D(t) > D_f] \\ &= \Phi_{\text{nor}}\left(\frac{\log(t) - [\log(D_f - \beta_1) - \mu]}{\sigma}\right), \end{aligned}$$

where $\Phi_{\text{nor}}(\cdot)$ is the standard normal cdf.

Example 5 [Analysis of weathering data using a random effects model]. This example uses the data shown in Fig. 2 which are subset of the data from Vaca-Trigo and Meeker [10]. The degradation model used here is the same as in Vaca-Trigo and Meeker [10]; that is,

$$\begin{aligned} D(t) &= \frac{A}{1 + \exp(-z)}, \quad \text{where} \\ z &= \frac{\log(t) - \beta_1}{\exp(\beta_2)}, \end{aligned}$$

t is the effective dosage, A is an unknown constant, and $\beta = (\beta_1, \beta_2)'$ is random from unit to unit. β is assumed to have a bivariate normal distribution with mean μ_β and covariance matrix Σ_β . The estimates for the unknown parameters A, μ_β , and Σ_β were obtained using the `nlme` function in R. The corresponding failure-time cdf $F(t)$ and the bootstrap confidence intervals, as shown in Fig. 5, were obtained using the algorithms in Meeker and Escobar [2, Sections 13.5.2 and 13.7].

Stochastic Models

Here, we introduce the Wiener process [7] and the Gamma process [8] which are stochastic models commonly used in the analysis of degradation data.

In the Wiener process model, the degradation path is given by

$$D(t) = \eta(t) + \sigma W[\eta(t)],$$

where $\eta(t)$ is a continuous monotone function reflecting trend and $W(t)$ is the standard Wiener process. See, for example, Cox

and Miller [13] for basic properties of the Wiener process. Under this model, the increments $\Delta\mathcal{D}(t) = \mathcal{D}(t + \Delta t) - \mathcal{D}(t)$ are independent and $\Delta\mathcal{D}(t)$ has a normal distribution with mean $\Delta\eta(t) = \eta(t + \Delta t) - \eta(t)$ and variance $\sigma^2|\Delta\eta(t)|$. For the Wiener process model case, $\mathcal{D}(t)$ has a nonmonotone and continuous path. The failure-time distribution induced by the degradation model (time to first crossing) is the inverse Gaussian distribution [14].

In some other applications [8], the degradation path $\mathcal{D}(t)$ can be modeled as a gamma process. For the gamma process model, the increments $\Delta\mathcal{D}(t) = \mathcal{D}(t + \Delta t) - \mathcal{D}(t)$ are independent and $\Delta\mathcal{D}(t)$ has a gamma distribution with a scale parameter ξ that is constant and a shape parameter equal to $\eta(t + \Delta t) - \eta(t)$, where $\eta(t)$ is a monotone increasing function of t . In this case, the degradation path $\mathcal{D}(t)$ is monotone increasing. The cdf $F(t)$ is related to the gamma function [9, Section 3].

Comparing the approximate method and the random effects path model, the stochastic process model is more advanced and requires a higher level of technical understanding. For examples where stochastic process model are used in the analysis of degradation data, see Whitmore [7], Lawless and Crowder [8], and Wang [9].

CONTINUOUS MONITORING

With the development of modern sensor and communications technology, degradation can be measured directly or indirectly in real time. Such information may also be called *system health* or *materials state* information, depending on the application. For example, aircraft engines, modern locomotives, and high-voltage power distribution transformers, system health/use rate/environmental data from a fleet of units in the field can be returned in real time to a data center. This information is used for real-time process monitoring and especially for prognostic purposes. If there is an appropriate signal in these data, rapid actions can be taken to avoid a serious system failure (e.g., by reducing the load on an unhealthy transformer). From a retrospective point of view, if some issue relating to system health arises at a

later date, it would be possible to look into the historical data that have been collected in search of causal effects. Sometimes, it is possible to find a detectable signal that could be used in the future to provide an early warning of the problem.

For example, Hahn and Doganaksoy [15, Section 9.9] describe an application involving modern locomotive engines installed with sensors that indicate the operating status such as oil pressure, oil temperature, and water temperature. Such data can be used to detect and avoid catastrophic failures by automatically shutting down a locomotive before serious damage occurs. In another application, high-voltage power transformers can be monitored by an automatic dissolved gas analyzer (DGA) system [16]. A DGA system performs periodic (typically every hour) analyses to indicate the presence of different kinds of dissolved gases in the transformer insulating oil. The chemical analyses can also measure moisture content. Certain combinations of dissolved gasses can signal a system health problem. In addition, a DGA system reports real-time dynamic loading and thermal information. This information is automatically transmitted to a control center and is useful for detecting faults that may lead to failure. Such information would enable operators to reduce the load on the transformer, or in an extreme case, to shut it down to avoid a costly failure.

FURTHER READING

This section provides a short list of useful reference in reliability. Meeker and Escobar [2, Chapters 13 and 21] introduce the concepts of degradation analysis and their relationship with the product reliability. They discuss the methods for data analysis and reliability inference for degradation data with numerous illustrations from real applications. Bagdonavičius and Nikulin [17, Chapters 3 and 13] describe statistical models and methods in degradation models and the estimation of parameters at a higher technical level.

Gertsbakh [18] has written a book for researchers and practitioners in the areas of reliability and maintainability. It

introduces the theory of reliability and how the theory can be used to develop preventive maintenance scheduling. In the area of reliability centered maintenance, Moubray [1] introduces the concepts and techniques in condition-based maintenance and condition monitoring.

Acknowledgments

THE DECISION SCIENCES INSTITUTE

KRISHNA S. DHIR
Campbell School of Business
Berry College
Mount Berry, GA

Wickham Skinner described the origins of the discipline of Decision Sciences as “founded upon the hard-scrabble, frequently unpopular and scorned achievements of a small number of men and women who doggedly persisted in trying to find ways of making management more effective” [1]. Perhaps, Charles Babbage, the inventor of the computer, was the first to write, in 1832, about organizing the production process. Eli Whitney, Isaac Singer, Cyrus McCormick, Fredrick Taylor, and Henry Ford made major contributions to the organization of the production process, and the development of systematic planning and numerical analysis of manufacturing systems—the factories. F.W. Harris introduced modeling, Walter Shewhart demonstrated the advantages of production scheduling and controls, and LHC Tippet introduced sampling to measurement of work. Operations research demonstrated its promise in World War II, during which its principles were applied to great advantage to address the logistical challenges of moving men and materials. After great challenges of World War II, Frank and Lillian Gilbreth, Henry Gantt, and W. Edward Deming brought major advancements to time and motion studies, measurement of work, and statistical quality control [1]. In the 1950s, the discipline of decision analysis was still relatively nascent. It received a major boost in 1953, during which Irwin Bross wrote *Design for Decision* [2]. Others who made critical contributions to the discipline were Martin Starr, Jay Forrester, Herbert Simon, Oskar Morgenstern, John von Neumann, and George Dantzig. In 1960s, Howard Raiffa of Harvard University explored the process of decision making and choice when outcomes were uncertain [3]. With the advent of computers, various scholars, including coauthors

[4, 5], described how application of emerging technologies could mitigate the challenges posed by uncertainty. Linear programming software was just becoming available [6]. Before long, Lee [7] published his book on goal programming.

THE NICHE

In 1967, Dennis E. Grawoig was a chairman of the Department of Decision Sciences at Georgia State University. He was a visionary with an indomitable spirit of adventure, had an ever-expanding community of friends, and was continually creating new opportunities for students and colleagues. He quickly realized that faculty members of the various business schools, with particular interest in quantitative analysis of the decision-making process, needed a home in the form of an association that promotes their interest. Such faculty members were to be found in practically all functional areas of the broad discipline of business administration, including accounting, finance, marketing, organization behavior and theory, production and operations management, and strategic management. The new discipline of management information system was in its infancy. Grawoig understood that while addressing the managerial and administrative issues, the focus of the proposed association would cross disciplines. As such, he was keen that the association should be welcoming and open to all disciplinary orientations.

The early history of the Decision Sciences Institute has been well documented by Taylor [8]. The following narrative relies heavily on his account. On April 10, 1968, Grawoig wrote a letter to approximately a 1000 members of the faculty in various departments of collegiate schools of business at various academic institutions. In this letter, he outlined a vision for a new learned association “... for business faculty members interested in the quantitative area.” He envisaged that such an association would potentially promote scholarship through

“some publication ... to record research in our field.” He imagined that an association of this sort would meet the particular needs of the quantitatively oriented members of the business school faculty members by providing “a clearinghouse for recruitment.” He also foresaw that “meetings or seminars” could be organized under the auspices of such an association, “to provide a forum for coordination and discussion of quantitative methods programs, etc.” He inquired whether recipients of his letter would be interested in joining such an association [8]. In the 1960s, there was an Operations Management interest group active within the Academy of Management. However, some scholars in the discipline felt that at the Academy of Management the level of interest in the operational aspects of organizations was not adequate for their needs [9]. Grawoig’s query appealed to these scholars.

THE INSTITUTE IS FORMED

Grawoig’s query led to the next significant date in the history of the Institute, November 1, 1968. On that date, roughly 25 individuals responded to Grawoig’s initiative and gathered in Atlanta to hammer out a framework for a new association. Present among them were Al Heinlein, Albert Simone, George Summers, Charles Hubbard, and Roger Collons. At this session, Dennis Grawoig was elected executive director of the association, and a seven-member Executive Committee was constituted. They gave the association a preliminary name of *National Quantitative Methods Association*. However, by the time the minutes were being finalized, the formal name of the association had already emerged as the *American Institute of Decision Sciences*, with a catchy acronym of AIDS [8].

Bernard Taylor gives the credit for coining the name, American Institute of Decision Sciences, to Ann J. Hughes, a colleague of Grawoig in the Department of Decision Sciences at Georgia State University. Ann Hughes also developed the original logo for the Institute. The acronym was very apt because the very purpose of quantitative analyses of decision-making processes was to provide insights

that would *aid* decision makers in meeting their challenges. The Institute’s name was formally adopted along with the logo at the Executive Committee’s meeting in Columbus, Ohio, 2 weeks later on November 14, 1968. At this meeting, the Committee appointed Dennis Grawoig the first President of the Institute for a 1-year term. The Institute was subsequently incorporated in Atlanta, Georgia, on December 6, 1968 [8].

THE EARLY YEARS

The first conference of the Institute was held during October 30 and 31, 1969, hosted by Louisiana State University at New Orleans’ Bourbon Orleans Hotel. There were approximately 100 attendees. One month later, the Committee, now called the *Board of Directors*, met again to discuss the initiation of the institute’s first journal, *Decision Sciences*. Its first issue was published early in 1970. The Board members agreed on four areas of emphasis: (i) tutorials, (ii) original theoretical developments and extensions, (iii) application of quantitative methods in administration, and (iv) education and curriculum developments. The first editor of the journal was Albert Simone, who was later to become the President of the University of Hawaii, and subsequently, the President of the Rochester Institute of Technology [8].

The Institute rapidly gathered momentum. The second annual meeting in 1970, held in Dallas, Texas, attracted approximately 250 participants. At that point, the Institute membership had grown to 682. The same year, the Institute initiated a placement service. The Board of Directors also decided to create regional subdivisions. The first of these, the Midwest subdivision, was created in 1970. Southwest, Southeast, Western, and Northeast regional subdivisions followed, with all in place by 1972. In the following year, the Board instituted the Distinguished Service Award. In 1972, the national honorary organization for the Decisions Sciences discipline was started, called *Alpha Iota Delta*. Rodger Collons was its first President. In 1974, the newsletter, *Decision Line*, was initiated with Thad Green of Mississippi State University as its first editor [8].

A DISCIPLINE EVOLVES

The decades of the 1950s and 1960s constituted an exciting period for the discipline of Decision Sciences. Skinner describes this period as “the glory years, times of excitement and discovery ...” The leaders of the discipline “... were a kind of heroes, magicians, mysterious in dealing with forms of analysis little understood ...” [1]. As described by Skinner, dramatic changes brought about in the art and science of management through analytical techniques by a very few pioneers, who were highly successful in spite of their small population, upset the conventional arrangements of the academe. Those affected by the altered scheme of things were threatened. The counter attack described decision analytic approaches as consisting of “slick algorithms” and “merely theoretical, too impractical, limited, and simplistic to be of much use.” [1]. However, by mid-1970s, the arguments were more or less settled by dramatic benefits accrued by practitioners and industries, and Decision Sciences found acceptance among the community of scholars. Subsequently, decision scientists and members of the Decision Sciences Institute began to specialize, attending to specific problem areas such as simulation of complex technical systems through mathematical modeling and experimentation; allocation of resources through mathematical programming, including strategic planning through dynamic programming and goal programming; management of production and operations management; management of information systems; analysis of logistics; supply chain management; materials requirement planning; and service management. Application of decision analytical tools became widespread, making inroads into and interacting with other established disciplines, such as finance, marketing, medicine, biology, and even various social sciences. Specialized industries looked to Decision Sciences for benefits, as with management of health-care systems, environment, military systems, public and municipal services, and government. Today, a wide range of disciplines and methodological

approaches are routinely covered at the Decision Sciences Institute’s publications and annual meetings. These include accountability, data and information security, ethics, decision support systems, decision theory and analysis, e-commerce, expert systems, finance, hospitality management, innovative education, international business, knowledge management, logistics, management information systems, management science and operations research, organizational theory and leadership, production and operations management, project management, quality management and continuous improvement, statistical analysis and quantitative methods, strategic management, and supply chain management. Some new methods have evolved in recent years, and some old methods have been boosted with renewed interest. Among recently evolved methodologies, we find classification trees, tabu search, and neural networks. Data mining has renewed interest in some older methods, such as regression analyses and experimental design, being applied to large data sets [6].

In 1977, the Institute, still known as the *American Institute of Decision Sciences*, created the designation of Fellow to be awarded to members in recognition of distinguished achievement in the field of Decision Sciences. The award would be given to active supporters of the Institute who have made outstanding contributions to Decision Sciences in at least two of the following categories: research and scholarship, teaching and/or administration, and service to the Institute. The initial group of Fellows was the first seven Presidents of the American Institute of Decision Sciences, who held the office in turn from 1969 to 1977. These were Dennis Grawoig, George Summers, Roger Collons, Gene Groff, Albert Simone, Kenneth Uhl, and Lawrence Schkade. Since then, the list of Fellows has grown, and includes luminaries such as George Benson, Harvey Brightman, William Berry, Charles Bonini, Elwood Buffa, Richard Chase, Norman Chervany, Roscoe Davis, Ward Edwards, Fred Glover, Jack Hayya, Ira Horowitz, George Huber, Basheer Khumawala, Claude McMillan, Herbert Moskowitz, Paul Nutt, Howard

Raiffa, Aleda Roth, Thomas Schriber, Marion Sobol, Linda Sprague, Bernard Taylor, Andrew Vazsonyi, Christopher Voss, Clay Whybark, and Robert Winkler.

STEPPING BEYOND THE BORDER

By the end of its first decade, the Institute had already streamlined its constitution and bylaws. In 1980, the Executive Council was replaced by the current structure of the Board of Directors through the inclusion of the regional Vice Presidents who would be elected by the respective regional subdivisions. The Institute also began to attract members from outside the United States. Its first annual meeting outside the United States was held in November 1984 in Toronto, Canada. By mid-1980s, the American Institute of Decision Sciences was feeling the need to change its name to reflect its emerging international interests. Even as these events were underway, Dennis Grawoig announced his retirement in 1985, after a remarkable 17-year service to the Institute as its founder and only executive director. He was replaced by Carol Latta in 1986, who has continued to hold the office through the date of this writing. Two-years later, in November 1986, the Institute held its first annual meeting outside the North American continent, in Honolulu, Hawaii. The issue of the Institute's name change was finally settled by the emergence of "... widespread publicity associated with acquired immune deficiency syndrome, or as it is commonly known, AIDS." In 1986, the Institute officially changed its name to the Decision Sciences Institute and acquired a new logo based on the letter, D.

PRESIDENTS OF THE INSTITUTE

On completion of his first term as the first President of the Institute, Grawoig was persuaded to continue for a second term. Clay Whybark is the only other individual to have served two back-to-back terms as President. While the Institute has had only two executive directors, 42 individuals have served

as President of the Institute to date. These individuals are listed below:

1969–1971	Dennis E. Grawoig, Georgia State University
1971–1972	George W. Summers, University of Arizona
1972–1973	Rodger D. Collons, Drexel University
1973–1974	Gene K. Groff, Georgia State University
1974–1975	Albert J. Simone, Rochester Institute of Technology
1975–1976	Kenneth P. Uhl, University of Illinois at Urbana-Champaign
1976–1977	Lawrence L. Schkade, University of Texas at Arlington
1977–1978	Charles P. Bonini, Stanford University
1978–1979	John Neter, University of Georgia
1979–1981	D. Clay Whybark, University of North Carolina—Charlotte
1981–1982	Norman L. Chervany, University of Minnesota—Twin Cities
1982–1983	Linda G. Sprague, University of New Hampshire
1983–1984	Laurence J. Moore, Virginia Polytechnic Institute and State University
1984–1985	Sang M. Lee, University of Nebraska—Lincoln
1985–1986	Harvey J. Brightman, Georgia State University
1986–1987	William R. Darden, Louisiana State University
1987–1988	James M. Clapper, Wake Forest University
1988–1989	William L. Berry, Ohio State University
1989–1990	Bernard W. Taylor, Virginia Polytechnic Institute and State University
1990–1991	Ronard J. Ebert, University of Missouri—Columbia

1991–1992	Robert E. Markland, University of South Carolina
1992–1993	William C. Perkins, Indiana University
1993–1994	Larry P. Ritzman, Boston College
1994–1995	K. Roscoe Davis, University of Georgia
1995–1996	John C. Anderson, University of Minnesota—Twin Cities
1996–1997	Betty J. Whitten, University of Georgia
1997–1998	James R. Evans, University of Cincinnati
1998–1999	Terry R. Rakes, Virginia Polytechnic Institute and State University
1999–2000	Lee J. Krajewski, University of Notre Dame
2000–2001	Michaael J. Showalter, Florida State University
2001–2002	F. Robert Jacobs, Indiana University
2002–2003	Thomas W. Jones, University of Arkansas at Fayetteville
2003–2004	Barbara B. Flynn, Indiana University
2004–2005	Gary L. Ragatz, Michigan State University
2005–2006	Thomas E. Callarman, China Europe International Business School
2006–2007	Mark M. Davis, Bentley College
2007–2008	Kenneth E. Kendall, Rutgers University
2008–2009	Norma J. Harrison, China Europe International Business School
2009–2010	Ram Narasimhan, Michigan State University
2010–2011	G. Keong Leong, University of Nevada, Las Vegas
2011–2012	Krishna S. Dhir, Berry College
2012–2013	E. Powell Robinson, University of Houston

On April 1, 2013, Maling Ebrahimpour of University of South Florida—St. Petersburg will become the President of the Institute.

GOING GLOBAL

The Institute continued to grow and created non-US regional subdivisions. These were named Asia-Pacific, Europe, Indian subcontinent, and Mexico subdivisions, respectively. Starting in 1990, the Institute began holding biennial conferences outside the United States on a regular basis. These meetings have been held in Australia, Belgium, China, France, Greece, Mexico, Spain, Taiwan, and Thailand.

Similarly to Clay Whybark, Charles Bonini, too, attributes the success of the Decision Sciences Institute to the fact that it met a niche that was not being served by other academic or professional organizations [6]. Additionally, about the time when this Institute was formed, business education was becoming increasingly important part of academia. As they shook off their “trade school” image, business schools had started engaging in significant and rigorous academic research [10]. The Institute provided an excellent forum for faculty members to disseminate and seek collaborative efforts. Today, the Institute has become much broader in its focus. Charles Bonini points out that this broadening of scope goes beyond the fact that “the entire spectrum of quantitative techniques” has become “a significant part of management education.” [6]. The definition of Decision Sciences itself has evolved and today extends to a full gamut of emerging areas of interest, including health-care systems, supply chain systems, and even social responsibility. Applications have been most visible in production and operations management, management information systems, quality management and control, service operations, logistics, and other such areas. New perspectives continue to be developed, such as business analytics [11]. Wickham Skinner indicates that publicized areas of Decision Science, which are no less important, are “applications in finance,

marketing, biology, medicine and health systems, environmental policy, and government bureaus [1].” Nevertheless, the membership of the Institute peaked in 1991, held steady for the next about 8 years, and then began to decline at a rate of about 4% per year, until 2010. Certain innovations implemented in the annual programs in 2010 and 2011 have arrested the declining trends and increased participation by a dramatic 12.5%. However, through the years, the focus of the Institute shifted away from practical aspects of social and economic issues to topics of academic interest. Wickham Skinner examined the articles published in the Institute’s journal, *Decision Sciences*, and found that during 2007, an Institute membership of 1842 had produced merely seven articles that would be relevant and useful to practitioners [1].

THE INSTITUTE TODAY

The academic orientation of the Institute is evident in its assertions on the Institute’s official Web site, www.decisionsciences.org. The official Web site describes the Institute as “a professional organization of academicians and practitioners interested in the application of quantitative and behavioral methods to the problems of society.” However, the Web site adds that the Institute “plays a vital role in the academic community by offering professional development activities and job placement services.” In August 2008, the Board of Directors of the Institute adopted the following mission statement: “The Decision Sciences Institute advances the science and practice of decision making. We are an international learned society with an inclusive and cross-disciplinary philosophy. We are guided by the core values of high quality, responsiveness, and professional development.” The Institute’s vision is articulated as “The Decision Sciences Institute is dedicated to excellence in fostering and disseminating knowledge pertinent to decision making.” In its activities, the Institute places great emphasis on innovative education through focus on curriculum development, pedagogy, and career development. Nearly 90% of the Institute’s members are academics. A great

proportion of stakeholders among the academics are untenured faculty members who are under pressure to publish and establish themselves as scholars. Skinner describes them as the “slaves” of the academic society [1]. It is impractical for untenured faculty members to alter the priorities of the academic society. Skinner calls on those members of the academy and Institute who are tenured and those who administer the academic system to change the direction of business education and, indeed, Decision Science.

A CALL TO RELEVANCE

He reminds us that the purpose of Decision Science is to “help decision makers make better decisions.” [1]. To return the practical, “real” world from a culture of writing papers for academic peers, the Institute members need to reexamine their methodologies, reemphasize research based on empiricism, and reconnect with the practitioner. Skinner had a vision of the Decision Sciences Institute spearheading the effort to redefine the “mission, objectives, processes, and practices of Decision Sciences . . .” We exist in an environment of constant and rapid change characterized by “a high density of big, serious, varied and widely dispersed societal problems.” [1]. He cites specific issues that the discipline of Decision Science should take on to return to its glory years. These include issues pertaining to declining standard of living in the United States, rise in the negative balance of trade, climate change, weakness of the public schools, engineering and research moving offshore, federal deficits, continuing the increase in the volume of US manufacturing, apparent distaste of our workforce to work in factories, counterterrorism, and shortages of oil, food, and water [1]. This vision has implications for the way in which we practice Decision Science. Instead of engaging solitary academic research on hypothesized problems, we would have to talk to the practitioners, work in teams, be willing to cross into the boundaries of unfamiliar disciplines, collaborate with those who apply Decision Science in the “real” world—the practical decision makers, and engage in empirical research. Moreover, we have to collaborate with those who

are in disciplines different from our own, and share our intellectual property with others.

THE EXPONENTIALLY WEIGHTED MOVING AVERAGE

MARCUS B. PERRY
Department of Information
Systems, Statistics and
Management Science, The
University of Alabama,
Tuscaloosa, Alabama

DEFINITION

The exponentially weighted moving average (EWMA) is often applied to a time-ordered sequence of random variables. It computes a weighted average of the sequence by applying weights that decrease geometrically with the age of the observations. The EWMA is parameterized by the following. Consider the $n \times 1$ random vector $\mathbf{x}$ given by

$$\mathbf{x} = [x_1, x_2, \dots, x_n]', \quad (1)$$

with mean vector $\boldsymbol{\mu}$ and finite $n \times n$ autocovariance matrix Σ . The EWMA is defined by the linear transformation

$$\mathbf{z} = \mathbf{C}\mathbf{x} + z_0\mathbf{b}, \quad (2)$$

where $\mathbf{z}$ is $n \times 1$ and

$$\mathbf{C} = \begin{pmatrix} \lambda & 0 & 0 & \dots & 0 \\ \lambda(1-\lambda) & \lambda & 0 & \dots & 0 \\ \lambda(1-\lambda)^2 & \lambda(1-\lambda) & \lambda & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \lambda(1-\lambda)^{n-1} & \lambda(1-\lambda)^{n-2} & \lambda(1-\lambda)^{n-3} & \dots & \lambda \end{pmatrix} \quad (3)$$

is a known $n \times n$ matrix and $\mathbf{b}$ is a known $n \times 1$ vector having the form

$$\mathbf{b} = ((1-\lambda) \quad (1-\lambda)^2 \quad \dots \quad (1-\lambda)^n)', \quad (4)$$

where z_0 is an initial (scalar) value and denotes the starting value for the EWMA. The parameter λ ($0 < \lambda \leq 1$) is called the *smoothing* coefficient and its value in practice is often selected based upon how fast the process mean changes. For more rapid mean changes one should choose λ to be “large” and for slower (or less frequent) mean changes one should choose λ to be “small.” In applications such as forecasting, λ is typically chosen between 0.05 and 0.30 [1] and [2]. It should be noted that when $\lambda = 1$ we have $\mathbf{z} = \mathbf{x}$. This is evident from Equation (2), when $\lambda = 1$ we have $\mathbf{C} = \mathbf{I}$ (where $\mathbf{I}$ is the identity matrix) and $\mathbf{b} = \mathbf{0}$ so that,

$$\mathbf{z} = \mathbf{C}\mathbf{x} + z_0\mathbf{b} = \mathbf{I}\mathbf{x} + z_0\mathbf{0} = \mathbf{x}. \quad (5)$$

To illustrate the EWMA, Fig. 1 shows a plot of $n = 100$ observations randomly generated from a normal process with a time-varying mean. The original process $\{x_i\}$ is shown as the dotted line and the EWMA process $\{z_i\}$ ($\lambda = 0.20$) is shown as the solid line. For this realization, the initial value z_0 was set to zero. The value of $\lambda = 0.20$ was chosen by minimizing the sum of the squared one-step-ahead prediction errors. This will be discussed in more detail later.

Properties

By applying the expectation operator to Equation (2), it is easily shown that

$$\mathbf{E}(\mathbf{z}) = \mathbf{C}\boldsymbol{\mu} + z_0\mathbf{b}, \quad (6)$$

and by letting $\boldsymbol{\mu} = \mu\mathbf{1}_{n \times 1}$ (i.e., stationary mean) and $z_0 = \mu$ we have

$$\begin{aligned} \mathbf{E}(\mathbf{z}) &= \mu\mathbf{C}\mathbf{1}_{n \times 1} + \mu\mathbf{b} \\ &= \mu(\mathbf{C}\mathbf{1}_{n \times 1} + \mathbf{b}) = \mu\mathbf{1}_{n \times 1}, \end{aligned} \quad (7)$$

Figure 1. EWMA of a single simulated realization.

where $\mathbf{1}_{n \times 1}$ is a $n \times 1$ vector of ones. In addition, the $n \times n$ autocovariance matrix of $\mathbf{z}$ is given by

$$\text{Var}(\mathbf{z}) = \text{Var}(\mathbf{C}\mathbf{x} + z_0\mathbf{b}) = \mathbf{C}\Sigma\mathbf{C}' = \sigma_x^2\mathbf{C}\mathbf{R}\mathbf{C}', \quad (8)$$

where $\mathbf{R}$ denotes the $n \times n$ autocorrelation matrix of $\mathbf{x}$. The i th diagonal element of Equation (8) is the variance of the EWMA process at time i , and the (i, j) th off-diagonal element is the autocovariance of the EWMA process at $\text{lag}(i-j) = \text{lag}(j-i)$. It can be shown that the variance of z_i at any time $i > 0$ can be written explicitly as

$$\begin{aligned} \text{Var}(z_i) = \sigma_x^2 \lambda^2 & \left(\sum_{j=0}^{i-1} (1-\lambda)^{2j} \right. \\ & \left. + 2 \sum_{k=0}^{i-2} \sum_{\ell=k+1}^{i-1} (1-\lambda)^{k+\ell} \rho_{\ell-k} \right), \end{aligned} \quad (9)$$

where $\rho_m = \rho_{-m}$ denotes the lag m autocorrelation of the original process $\{x_i\}$. It should

be noted that $\text{Var}(z_i) \rightarrow \sigma_z^2$ as $i \rightarrow \infty$, where σ_z^2 denotes the steady-state variance of the EWMA process and can be written as

$$\sigma_z^2 = \sigma_x^2 \left(\frac{\lambda}{2-\lambda} + 2\lambda^2 \sum_{k=0}^{\infty} \sum_{\ell=k+1}^{\infty} (1-\lambda)^{k+\ell} \rho_{\ell-k} \right), \quad (10)$$

where the last term converges, as $|(1-\lambda)^{k+\ell} \rho_{\ell-k}| < 1$ for all k and ℓ . Note that for uncorrelated processes Equation (10) reduces to

$$\sigma_z^2 = \sigma_x^2 \left(\frac{\lambda}{2-\lambda} \right). \quad (11)$$

In the next section, some discussion on EWMA forecasts is provided. In subsequent sections, application of the EWMA to sales forecasting and quality control applications are presented. Finally, this tutorial will close with a discussion.

COMPUTING EWMA FORECASTS

The EWMA forecast of a future observation at time $n + \ell$ is calculated by

$$\hat{x}_{n+\ell} = z_n = \lambda \sum_{j=0}^{n-1} (1-\lambda)^j x_{n-j} + (1-\lambda)^n z_0, \quad (12)$$

where for large n the last term is negligible and the forecast at the time $n + \ell$ can be written as

$$\hat{x}_{n+\ell} = z_n = \lambda \sum_{j=0}^{n-1} (1-\lambda)^j x_{n-j}. \quad (13)$$

Note that the forecasts generated by Equation (12) are the same for all lead times $\ell > 0$. To update forecasts with each new observation, one can use

$$z_n = \lambda x_n + (1-\lambda)z_{n-1}, \quad (14)$$

which can also be written as

$$z_n = z_{n-1} + \lambda(x_n - z_{n-1}), \quad (15)$$

where Equation (15) is written as the sum of the previous period's forecast and a fraction of the previous period's forecast error.

Suppose one uses z_n to forecast x_{n+1} , then for long running processes the variance of the one-step-ahead prediction error ($z_n - x_{n+1}$) is given by

$$\sigma_{\text{pred}}^2 = \sigma_z^2 + \sigma_x^2 \left(1 - 2\lambda \sum_{j=0}^{n-1} (1-\lambda)^j \rho_{j+1} \right), \quad (16)$$

where σ_z^2 is the steady-state EWMA variance, σ_x^2 is the steady-state variance of the original process $\{x_i\}$, and ρ_m denotes the lag m autocorrelation of $\{x_i\}$. Notice that for uncorrelated processes $\rho_m = 0$ ($m \neq 0$) and Equation (16) reduces to

$$\sigma_{\text{pred}}^2 = \sigma_z^2 + \sigma_x^2, \quad (17)$$

which is the sum of the steady-state variances of the EWMA process and the original

process. More generally, the variance of the prediction error is defined for all lead times $\ell > 0$ by

$$\sigma_{\text{pred}}^2 = \sigma_z^2 + \sigma_x^2 \left(1 - 2\lambda \sum_{j=0}^{n-1} (1-\lambda)^j \rho_{j+\ell} \right). \quad (18)$$

Initial Value for z_0

As noted previously, the influence of z_0 on z_n is negligible for large n . Thus, if n is large, one can choose any value for z_0 and its effect on z_n should be null. Some guidance for selecting z_0 in practice is given in Abraham and Ledolter [1], where these authors suggest using the arithmetic average of available historical data as the starting value.

Choice of Smoothing Coefficient

The smoothing coefficient λ determines how much the current observation affects the forecast. As mentioned previously, a small λ applies more weight to the previous observations and less weight to the current observation (and vice versa for large λ). Selection of values for λ in practice is typically accomplished via simulation. Specifically, forecasts are computed for a range of values of λ and are compared to the actual observations $x_1, x_2, \dots, x_n$. For each value of λ , the one-step-ahead forecast errors are computed by

$$e_{i-1} = x_i - z_{i-1}, \quad (19)$$

for $i = 1, 2, \dots, n$, and the sum of squared one-step-ahead forecast errors are computed by

$$\text{SSE}(\lambda) = \sum_{i=1}^n e_{i-1}^2, \quad (20)$$

where the smoothing coefficient λ that minimizes Equation (20) is then used to compute future forecasts.

To illustrate, consider the time series shown in Fig. 2. The data were simulated from an independent normal process with a time-varying mean. Suppose one considers values of $\lambda \in [0.05, 0.30]$ in increments of

Figure 2. Single realization of simulated time series.

Figure 3. Plot of λ versus $SSE(\lambda)$ for simulated series.

0.05, and computes $SSE(\lambda)$ for each of these cases (i.e., $\lambda = 0.05, 0.10, 0.15, \dots, 0.30$). Figure 3 shows a plot of λ versus $SSE(\lambda)$ for the series shown in Fig. 2. Since $\lambda = 0.15$ yields the minimum sum of squared (one-step-ahead) prediction errors, this value will be used to compute future forecasts.

The EWMA process $\{z_i\}$ with $\lambda = 0.15$ is shown in Fig. 4, superimposed on the original process $\{x_i\}$. The $(n + \ell)$ th forecast ($\ell > 0$) for this process is then computed by

$$\hat{x}_{n+\ell} = z_{n-1} + 0.15(x_n - z_{n-1}). \quad (21)$$

Figure 4. Original series $\{x_i\}$ and EWMA series $\{z_i\}$ ($\lambda = 0.15$) superimposed on same plot.

Figure 5. Single realization of simulated AR(1) process.

Consider the second example, where the process under study is well modeled by the first-order autoregressive process, or AR(1), given by

$$x_i = \mu + \phi(x_{i-1} - \mu) + \epsilon_i, \quad (22)$$

for $i = 1, 2, \dots, n$, where $|\phi| < 1$ denotes the autoregressive parameter and the ϵ_i 's are uncorrelated with constant variance σ_ϵ^2 . A single realization of the AR(1) process with $\mu = 0$, $\phi = 0.60$, and $\sigma_\epsilon^2 = 1$ is shown in Fig. 5. Considering a range of $\lambda \in [0.15, 0.90]$

in increments of 0.15, Fig. 6 shows the value of λ that yields the minimum $SSE(\lambda)$ is $\lambda = 0.60$. This is no surprise since the lag 1 autocorrelation for the AR(1) process with $\phi = 0.60$ is $\rho_1 = 0.60$. Figure 7 shows the EWMA process $\{z_i\}$ with $\lambda = 0.60$

superimposed on the original process $\{x_i\}$. For this example, $\lambda = 0.60$ should be used to compute future forecasts, where the forecast at time $n + \ell$ ($\ell > 0$) is given by

$$\hat{x}_{n+\ell} = z_{n-1} + 0.60(x_n - z_{n-1}). \quad (23)$$

Figure 6. Plot of λ versus $SSE(\lambda)$ for realization of AR(1) process.

Figure 7. Original series $\{x_i\}$ and EWMA series $\{z_i\}$ ($\lambda = 0.60$) superimposed on same plot.

In the next section, some of the most common applications of the EWMA are discussed to include forecasting and application of the EWMA to quality engineering problems.

APPLICATIONS OF THE EWMA

One of the most common applications of the EWMA is generating one-step-ahead forecasts of time series. For example, consider Fig. 8, where the monthly Australian sales of rose wine is plotted over 173 months, from approximately January 1980 to April 1995. The data and its original source can be obtained from the Time Series Data Library.¹ Suppose we consider values of $\lambda \in [0.05, 0.30]$ in increments of 0.05, then the plot in Fig. 9a shows the value of λ , which minimizes $SSE(\lambda)$ is $\lambda = 0.15$. The plot in Fig. 9b shows the EWMA with $\lambda = 0.15$ superimposed on the same plot as $\{x_i\}$. The forecast for x_{174} is then given by $\hat{x}_{174} = z_{173} = 47.23$. The actual sales in the 174th month is $x_{174} = 45.00$, and the forecast error is given by $e_{173} = -2.23$.

Another common application of the EWMA is in quality control applications. Roberts [3] was the first to suggest the use of EWMA as the basis for a process monitoring and control scheme (i.e., control chart). The idea is to chart the z_i at each time i and compare to an upper and lower control limit. If z_i exceeds one of these control limits, then the process is deemed “out of statistical control.” Specifically, at each time $i > 0$, the EWMA z_i is compared to the control limits

$$\mu_0 \pm L\sqrt{\text{Var}(z_i)}, \quad (24)$$

where μ_0 is the expected value of the process, $\text{Var}(z_i)$ is defined in Equation (9) and L is a constant expressed in standard deviation units.² If z_i exceeds one of the control limits in Equation (24), then one would conclude with strong evidence that the process mean

has shifted. It is common in practice to use the steady-state control limits, which is given by

$$\mu_0 \pm L\sqrt{\sigma_z^2}, \quad (25)$$

where σ_z^2 is defined in Equation (10).

To illustrate the application of the EWMA control chart, consider the statistical monitoring of an industrial process to assess its quality over time. Suppose that the expected (or in-control) mean value of the original process $\{x_i\}$ is $\mu_0 = 0$, that samples taken over time are uncorrelated, and the variance of $\{x_i\}$ is given by $\sigma_x^2 = 1$. Suppose further that following the 50th sample collected, the process mean shifts from $\mu_i = 0$ to $\mu_i = 1$, so that the 51st sample collected is the first obtained from the changed process. Then the plot in Fig. 10a shows a single realization of this process. The plot in Fig. 10b shows the EWMA control chart; which signaled at $n = 58$, which implies eight observations were sampled from the changed process before the control chart issued a signal. Notice that the control chart limits reach steady-state after roughly 15 observations.

The above illustration is an example of how the EWMA can be used as the basis for a process change detection algorithm. Although the process in the latter example is uncorrelated, the EWMA can be used to monitor autocorrelated processes as well [4–6]. For more details on the development, design, and application of the EWMA control chart see Roberts [3], Hunter [7], Montgomery [2], and Lucas and Saccucci [8].

The above examples are not the only applications of the EWMA; however, they are common applications of the EWMA in the management science and quality engineering disciplines. In general, application of the EWMA is widespread throughout several disciplines, including health, finance, criminal justice, sports, industry, demography, and many more.

DISCUSSION

In this tutorial, the EWMA was discussed. As previously noted, EWMA is frequently

¹The Time Series Data Library is accessible at <http://www.robjhyndman.com/TSDL/>.

²The constant L is typically chosen based upon an acceptable false alarm rate.

used to compute short-term forecasts of time series (e.g., sales, stocks, and so on). It is also used as a basis for developing process monitoring and control schemes. Further, some properties of the EWMA, to include its expected value and variance, as well as the ℓ -step ahead forecast error variance were provided. Some discussion on computing EWMA forecasts was also included, as well as a commonly used method for selecting a value for λ in practice. Finally, some common applications of the EWMA in the management science and quality engineering disciplines were discussed.

GENERAL INTRODUCTION

Reliability is the probability that a system, vehicle, machine, device, and so on, will perform its intended function under operating conditions, for a specified period of time [1, p. 2]. As suggested by Condra [2], reliability can also be defined as “quality over time.” It has been recognized, however, that achieving and improving high reliability requires careful focus on the time dimension, which lies beyond the standard tools used in quality control and improvement.

Reliability data are usually collected to assess product reliability. Failure-time data, which record the time-to-failure of units, are one of the most common and important types of reliability data. Statistical models and methods for such data play an important role in reliability. An important task of statistical analysis in the failure-based paradigm is to estimate product reliability based on available failure-time data. These estimates can be used to answer questions that are related to product reliability such as what will be the fraction failing for the next six months, or how much improvement in reliability can be expected if a new design is used.

Other than failure-time information, system-condition information can also be

used to assess system reliability and plan maintenance. This area is different from the failure-time analysis focus in this article. See Hong *et al.* [3] for an introduction to the condition-based paradigm.

The rest of this article describes the main sources and characteristics of failure-time data, commonly used reliability metrics, the analysis of failure-time data with explanatory variables, and the analysis of failure-time data with competing risks. Some trends in reliability data and further reading are suggested.

SOURCES OF FAILURE-TIME DATA

Failure-time data come mainly from two sources: laboratory life tests and the field. *Life test data* usually come from regular life tests or accelerated life tests. Laboratory tests are often done to study durability, wear rate, or other lifetime properties of particular materials or components. Tests are also done at a subsystem or complete system level. For example, Meeker [4] reports results from an integrated circuit life test.

An “accelerated test” can be used to obtain information in a timely manner for components that last for years or even decades. In the accelerated test, units are tested at high levels of cycling rate, temperature, voltage, stress, or some other accelerating variable to get reliability information quickly. Extrapolation based on a physically motivated model is often needed to get reliability information under the conditions of use. Nelson [5] gives examples, models, and data on accelerated test. Escobar and Meeker [6] provide a detailed review of accelerated test models.

Field data usually come from warranty databases or field tracking studies. Warranty databases, which were initially created for financial-reporting purposes, also provide a rich source of reliability information. Warranty data are generally heavily censored (i.e., not all units fail during the warranty period; see the section titled “Characteristics

of Failure-Time Data” for more details) because little or no information can be obtained after a product is out of warranty. Kalbfleisch *et al.* [7] give an example of failure-time data from an automobile warranty database.

For some products, careful field tracking can provide good reliability data. Examples include medical devices and a company’s fleet or fleets of assets. Hong *et al.* [8] give an example of a field tracking study of lifetimes of an energy company’s fleet of high-voltage power transformers.

CHARACTERISTICS OF FAILURE-TIME DATA

Failure-time data are typically censored (failure times are not known exactly). The most common reason for censoring is the need to analyze data before all units fail. Censored observations provide a bound or bounds on the actual failure times. Censoring arises in different forms such as right censoring, left censoring, and interval censoring.

For a right-censored observation, we have a lower bound on the failure time. Type I (time) censoring results when a sample of units is put on test and the units are tested simultaneously until the test is stopped at a particular time. See Meeker and Escobar [1, Examples 1.2 and 1.3] for examples. Type II (failure) censoring is less common in practice and arises when a life test is terminated after a specified number of failures have been observed. Units can be censored at different censoring times, causing multiple censoring. Multiply-censored data can result from staggered entry (units put into the field or on test at different times) or due to random censoring. Random censoring can arise from competing-risks data. For example, when a product can fail due to two or more causes of failure [1, Example 3.8] and the primary focus is on a particular cause of failure, failures from other causes can be considered as randomly censored. When the multiple causes of failure are not independent, random censoring is informative and the analysis is more complex [9,10].

Left censoring and interval censoring also arise in failure-time data. For a left-censored

observation, we have an upper bound for the failure time. For interval censoring, we know both, the lower and upper bounds for a failure time.

Truncation is similar to censoring but with an important difference. Truncation arises when only those units whose failure time lie within a certain time window are observed. The existence of units outside that window is unknown. For the censored data case, however, we have at least partial information on each unit. Like censoring, truncation can also arise as left truncation, right truncation, interval truncation, and so on. See Kalbfleisch and Lawless [11], Meeker and Escobar [1], and Hong *et al.* [8], for some examples.

Example 1 [Bearing-cage field data].

This is an example with multiple censoring. Figure 1 shows an event plot for bearing-cage fracture times for six failed units as well as running times for 1697 units that had accumulated various amounts of service time without failing. The data and analysis were given initially in Abernethy *et al.* [12]. The data are multiply censored because the failure times are intermixed with the censored times.

BASIC RELIABILITY METRICS

Here, we introduce some basic reliability metrics. An important goal of statistical analysis is to estimate one or more of these quantities and use confidence intervals to quantify statistical uncertainties.

The time-to-failure random variable is denoted by T . Here, T is a positive quantity because the failure time of a product or a component is always positive. The cumulative distribution function (cdf) of T is denoted by $F(t) = \Pr(T \leq t)$, giving the fraction of the population failing at time t . The reliability function (rf), also known as survival function, is defined by $R(t) = \Pr(T > t) = 1 - F(t)$, which gives the fraction surviving at time t . The probability density function (pdf) for a continuous random variable is defined as $f(t) = dF(t)/dt$, the first derivative of $F(t)$ with respect to t .

Figure 1. Event plot of bearing-cage field data (* indicates failed units, → indicates censored units).

The quantile function t_p gives the time for observing a specified proportion p of the population failing. Note that t_p is the inverse function of the cdf; that is, $t_p = F^{-1}(p)$ if $F(t)$ is strictly increasing. For example, $t_{0.10}$ is the time by which 10% of the population will fail.

The hazard function (hf), defined as

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr(t < T \leq t + \Delta t \mid T > t)}{\Delta t} = \frac{f(t)}{1 - F(t)}$$

gives the propensity to fail in the next small interval of time for units that have survived to the beginning of that interval. There is a connection between the shape of the hf and the type of failure mode (cause of failure). For example, an increasing hf corresponds to aging/wear out and a decreasing hazard function generally suggests a mixture of defective or other weak units leading to infant mortality. The cumulative hf is defined as $H(t) = \int_0^t h(x) dx$. The relationship between $F(t)$ and $H(t)$ is $F(t) = 1 - \exp[-H(t)]$. Figure 2 gives plots

of the cdf, pdf, rf, and hf for an example distribution.

The mean time-to-failure (MTTF) also appears in the reliability literature as a measure of the central tendency of T . The MTTF is defined by $E(T) = \int_0^\infty tf(t) dt = \int_0^\infty [1 - F(t)] dt$. When the distribution of T is highly skewed, the MTTF may differ appreciably from other measures of central tendency like the median, $t_{0.5}$. MTTF, for historical reasons, is often used as a reliability metric when it should not be used. In particular, MTTF has little or no practical meaning to describe the failure-time distribution of a component or system that has only a small probability of failing during its technological life. For such components and systems, a failure probability or a lower-tail distribution quantile is much more appropriate.

NONPARAMETRIC ESTIMATION

Here, we introduce methods of nonparametric (model-free) estimation of $F(t)$. Once an estimate of $F(t)$ is available, the other functions such as $S(t)$ and $H(t)$, can be estimated

Figure 2. Plots of the cdf, pdf, rf, and hf for an example distribution.

using the relationships provided in the previous section. For complete (not censored) or right-censored data, the Kaplan–Meier (KM) estimator [13] is the most popular nonparametric estimator for $F(t)$. Details of how this estimator is computed can be found in, for example, Meeker and Escobar [1, Section 3.5]. The KM estimator is a step (staircase) up function of time that jumps at each failure time t_i by a quantity which is determined by the number of units at risk at t_i , the number of failures reported at t_i , and the number of units that have been censored prior to t_i . When there is no censoring, the KM estimate is the same as the empirical cdf estimate giving the fraction failing as a function of time. The KM estimator requires no assumptions about the form of the underlying distribution but it requires the assumption that censoring is not informative. The KM estimate is widely available in modern statistical software packages (e.g., JMP, MINITAB, R, SAS, and S-PLUS).

The KM estimator can be extended to handle data with other types of censoring and truncation. Peto [14] defined the nonparametric estimator of the cdf for arbitrary censoring, including complicated overlapping interval-censored data. Turnbull

[15] further generalized this estimator to allow for truncated data. The Peto–Turnbull estimator for censored data given in Turnbull [15] is also available in some reliability software packages.

Nelson [16] proposed a nonparametric estimator for the cumulative hf which can be converted to an estimate for $F(t)$ using the relationship $F(t) = 1 - \exp[-H(t)]$. Aalen [17] gave the corresponding asymptotic properties of this estimator.

Example 2 [KM estimate for the bearing-cage field data]. As shown in Fig. 1, the bearing-cage data come from a population of units that had been introduced into service over time. Analysts wanted to use these initial data to see if the bearing-cage design is adequate and decide if a redesign would be needed. The design-life specification was that $t_{0.10}$ be at least 8000 h. Figure 3 shows a KM estimate of the fraction failing as a function of hours. Because the largest reported time $t = 2050$ is a right-censored observation, the KM estimate is only defined up to that time. We can see that, in this application, the KM estimate, by itself, will not allow assessment of whether the design-life specification has been met.

Figure 3. Plot of the KM estimate of the cdf of the bearing-cage data.

PARAMETRIC MODELS AND PARAMETER ESTIMATION

Common Parametric Distributions for Failure-Time Data

Extrapolation is often needed for reliability estimation and prediction. For example, the fraction of a product failing after three years often needs to be estimated based on one-year data. Parametric models are needed for this purpose.

The distribution of a failure time T is often modeled with a log location-scale distribution. The Weibull and lognormal are the most commonly used distributions and are members of this family. The cdf of T from a log location-scale distribution can be expressed as

$$F(t; \mu, \sigma) = \Phi \left[\frac{\log(t) - \mu}{\sigma} \right], \quad t > 0, \quad (1)$$

where $\Phi(z)$ is the standard cdf for the location-scale family of distributions (with location parameter $\mu = 0$ and scale parameter $\sigma = 1$). The corresponding pdf is

$$f(t; \mu, \sigma) = \frac{1}{\sigma t} \phi \left[\frac{\log(t) - \mu}{\sigma} \right],$$

where $\phi(z) = d\Phi(z)/dz$ is the standard pdf corresponding to $\Phi(z)$. The cdf and pdf of the lognormal distribution can be obtained by replacing Φ and ϕ above with Φ_{nor} and ϕ_{nor} , the standard normal cdf and pdf, respectively. The cdf and pdf of a Weibull random variable can be obtained by using $\Phi_{\text{sev}}(z)$

$= 1 - \exp[-\exp(z)]$ and $\phi_{\text{sev}}(z) = \exp[z - \exp(z)]$, the standard (i.e., $\mu = 0, \sigma = 1$) smallest extreme value cdf and pdf, respectively. The cdf and pdf of the Weibull random variable can equivalently, but more commonly, be written as

$$F(t; \eta, \beta) = 1 - \exp \left[- \left(\frac{t}{\eta} \right)^\beta \right]$$

and

$$f(t; \eta, \beta) = \left(\frac{\beta}{\eta} \right) \left(\frac{t}{\eta} \right)^{\beta-1} \exp \left[- \left(\frac{t}{\eta} \right)^\beta \right],$$

where $\eta = \exp(\mu)$ is the scale parameter and $\beta = 1/\sigma$ is the shape parameter. The shape parameter β determines the shape of the Weibull hf. For example, if $\beta > 1$, the hf is increasing (corresponding to wear out). See, for example, Hahn and Shapiro [18, Chapter 8] and Meeker and Escobar [1, Chapters 4 and 5] for more details about these and other distributions that are commonly used to describe failure-time data.

Probability Plots

It is difficult for the human eye to compare data in plots like Fig. 3 with parametric cdfs like the cdf shown in Fig. 2. Probability plots display data on special probability scales such that the parametric cdf from every member of a specified family of distributions is a straight line when plotted on such a scale. For example, taking the logarithm of the Weibull quantile gives the straight line $\log(t_p) = \log(\eta) + (1/\beta) \log[-\log(1-p)]$,

which suggests plotting t on a logarithmic scale (usually on the x axis) and plotting p on a probability scale with the underlying transformation $\log[-\log(1-p)]$ (usually on the y axis), providing a Weibull probability plot. See Meeker and Escobar [1, Chapter 6] for more examples. Thus, appropriately plotting a nonparametric estimate on a probability plot, and assessing whether the plot reasonably approximates a straight line, provides a simple but effective assessment of the adequacy of an assumed distribution.

Example 3 [Probability plot of the KM estimate for the bearing-cage field data]. Figure 4 is a Weibull probability plot of the bearing-cage data showing the nonparametric estimate (the solid dots), plotted at a point half way up the jump in the KM estimate at each failure time. The dashed lines are approximate 95% nonparametric simultaneous confidence bands that help assess the sampling uncertainty in the estimate of $F(t)$. These confidence bands are obtained by using the method described in Nair [19], and are defined by the inversion of a distributional goodness-of-fit test. If a straight line can be drawn through the confidence bands, as is the case here, the distribution implied by the probability paper cannot be ruled out as a model that might have generated the data.

Maximum Likelihood (ML) Estimation of Parameters

The ML method provides a formal and objective statistical approach to fit a failure-time distribution based on an assumed model. For analysis of reliability data with censoring and using skewed distributions (e.g., the Weibull and the lognormal), the use of the ML method is strongly recommended. The idea behind the ML method is simple. For a given data set, one writes the probability of observing the data (or a function that is proportional to the probability of the data) for the proposed model as a function of unknown model parameters. This function is called the “likelihood function.” The ML estimates are those values of the parameters that maximize this likelihood function. For example, the Weibull likelihood function for the bearing-cage data is given by

$$\mathcal{L}(\mu, \sigma | \text{DATA}) = \prod_{i=1}^n \left\{ \frac{1}{\sigma t_i} \phi_{\text{sev}} \left[\frac{\log(t_i) - \mu}{\sigma} \right] \right\}^{\delta_i} \times \left\{ 1 - \Phi_{\text{sev}} \left[\frac{\log(t_i) - \mu}{\sigma} \right] \right\}^{1-\delta_i},$$

where $\delta_i = 1$ if t_i is an exact observation and $\delta_i = 0$ if t_i is a right-censored observation. Here n is the number of observations. A probability plot is also useful for displaying the ML estimate. This estimate will appear as a straight line on the Weibull probability plot (Fig. 5).

Figure 4. Weibull probability plot for the bearing-cage fracture data along with nonparametric approximate 95% simultaneous confidence bands.

Figure 5. Weibull probability plot with the Weibull ML estimate and a set of pointwise approximate 95% confidence intervals for $F(t)$ for the bearing-cage field data.

Parametric ML estimation for data with arbitrary censoring and truncation is a natural extension of the likelihood for the right-censored data illustrated here. More details can be found in Meeker and Escobar [1].

Example 4 [Probability plot showing ML estimates for the bearing-cage field data]. Figure 5 is a Weibull probability plot for the bearing-cage data with the fitted ML line. The dotted lines depict a set of 95% parametric pointwise normal-approximation confidence intervals which are used to quantify statistical uncertainties due to limited data. See Meeker and Escobar [1, Chapter 8] for details about the computations.

REGRESSION ANALYSIS

Regression analysis of failure-time data from accelerated testing and field data with explanatory variable(s) can be useful to explain variability in failure-time data. In accelerated tests, test units of a material, component, subsystem, or entire systems are subjected to higher-than-usual levels of one or more accelerating variables such as temperature or stress. The accelerated test results are used to estimate the failure-time distribution of the units at use conditions. Regression models are needed for extrapolation to the use condition.

The single distribution models in Equation (1) can be extended to regression models. See Lawless [20] or Meeker and Escobar [1, Chapter 17] for details on parametric regression models and data analysis for failure-time data. In the most commonly used parametric failure-time regression model, the location parameter μ is modeled as a function of a vector of explanatory variables $\mathbf{x}$. For example, in a simple regression case, $\mu(\mathbf{x}) = \beta_0 + \beta_1 x_1$ where β_0, β_1 are the regression coefficients and x_1 is the univariate explanatory variable. For categorical variables, dummy variable coding is needed.

In a general case, $\mu(\mathbf{x}) = g(\mathbf{x}, \boldsymbol{\beta})$, where $\mathbf{x} = (1, x_1, x_2, \dots, x_p)'$ is a vector of explanatory variable, $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)'$ is the regression coefficient vector, and $g(\cdot, \cdot)$ is a general relation function specified by the model for a model that is linear in the parameter, $g(\mathbf{x}, \boldsymbol{\beta}) = \mathbf{x}'\boldsymbol{\beta}$. The ML method can be used to estimate $\boldsymbol{\beta}$ even in the presence of censoring and/or truncation.

Example 5 [Regression analysis of transformer lifetime data]. This is an example to illustrate the simple regression analysis of failure-time data with one explanatory variable. More complicated regression examples and regression analysis of data from accelerated tests can be found in Meeker and Escobar [1, Chapters 17 and 19].

We use a subset of the transformer failure-time data analyzed in Hong *et al.* [7]. The

Figure 6. Weibull probability plot showing the parametric regression estimates of the transformer failure-time distribution.

data used here are the failure-time data from a fleet of high-voltage power transformers from an energy company installed after 1987. More details about the data can be found in Hong *et al.* [7]. The explanatory variable here is the manufacturer of transformers which has two levels. This categorical variable is coded as a dummy variable (e.g., $x_1 = 0$ for Manufacturer A and $x_1 = 1$ for Manufacturer B). Figure 6 is the Weibull probability plot showing the parametric regression estimates of the transformer lifetime data. This figure suggests that the transformers from Manufacturer B are more reliable.

MULTIPLE FAILURE MODES AND COMPETING RISKS

Multiple failure modes failure-time data arise when products can fail due to different causes. For some applications, the cause of failure can be identified and it is often important to distinguish among different failure modes when analyzing the failure-time data. Some possible reasons for this are as follows:

- When failure modes behave differently, it is generally easier to find well-fitting failure-time distributions for the individual failure modes [1, Example 15.6].
- Some failure modes that could cause serious harm are of critical importance while others are not.

- Some failure modes are much more expensive to fix than others when predicting warranty costs.
- Knowledge of the relative frequency of different failure modes and the effect of eliminating one or more of the individual failure modes is important for engineers from a product design point of view. In particular, such information is important for providing focus on methods for improving reliability in the next generation of the product.

The theory of competing risks provides the appropriate statistical model for failure-time data with multiple failure modes. David and Moeschberger [21] describe the theory of competing risks. For single distribution applications in reliability, these methods are described and illustrated with examples in Nelson [22, Chapter 5], Meeker and Escobar [1, Chapter 15], and Crowder [9].

When failure-mode information is available for all failed units and the different failure modes can be assumed to be statistically independent, data analysis is similar to data analysis for single failure mode. When failure-mode information is missing for some or all of the failed units (i.e., masked causes of failure), the analysis is more complicated and needs special methods. Flehinger *et al.* [23] describe statistical methods for dealing with masked failure-mode data. When the

Figure 7. A Weibull probability plot showing ML estimates for the failure-time distribution of the individual failure modes and the system for Device G.

failure times for different failure modes are dependent, one approach is to use a multivariate failure-time model. In practice, however, there is often not enough information to identify such a model [10, Figure 7]. The subdistribution functions which give the fraction failing due to individual failure modes [9, p. 4], however, are always identifiable and sufficient for the data analysis in some applications.

Example 6 [Device G data]. The background for this data set is given in Meeker and Escobar [1, Example 15.6]. Device G is a component of a large system that had two failure modes: failure mode S and W, corresponding to electrical surges and wear out. The field tracking study data are available in Meeker and Escobar [1, Table 15.1]. The Weibull distribution was used to fit the failure time of individual failure modes assuming the independence of the two failure modes. Figure 7 is a Weibull probability plot showing the ML estimates for the individual failure modes. The curved line is the estimated series system failure probability for the two failure modes combined under the independence assumption, and it agrees well with the nonparametric estimate computed by ignoring the failure-mode information. Figure 8 shows the estimated hf for the failure time of Device G. The hf $h(t)$ shows an interesting “U” shape. This is because $h(t) = h_S(t) + h_W(t)$

where $h_S(t)$ and $h_W(t)$ are the hfs for Mode S and Mode W, respectively. Mode S has a decreasing hazard and dominates system failure early in life. Mode W has an increasing hazard and dominates system failure late in life.

NEW TRENDS IN FIELD RELIABILITY DATA

The next generation of reliability field failure-time data will be richer in information due to changes in data collecting technology (e.g., sensors and smart chips built into systems to measure environmental variables like stress and temperature). In some applications, this information is available dynamically. For example, medical systems (such as CAT scanners) and high-end printers and copiers can be connected to the network, providing such information on demand.

Use rate and environmental conditions are important sources of variability in product failure times. The most important differences between controlled laboratory accelerated test experiments and field reliability results are the uncontrolled operating and environmental field variation. This variation is from unit-to-unit and temporal, caused by variables such as use rate, vibration, temperature, and humidity. In the past, use-rate/environmental data has not been generally available in reliability

Figure 8. The estimated hazard function for Device G.

data analysis. In the future, failure-time models that use use-rate/environmental data will have the potential to explain much more variability in field data than has been possible before. The information can also be used to predict future environmental conditions and thus provide better information for predicting failure times.

FURTHER READING

This section provides a short list of useful references in reliability. Meeker and Escobar [1] describe commonly used statistical methods for reliability data analysis, providing a large number of examples and sufficient technical detail to understand how and why the methods work. Lawless [20] is an important reference for some of the technical aspects of statistical methods for failure-time data, illustrating methods with both engineering and medical applications. Tableman and Kim [24] describe methods for analyzing time-to-event data and illustrate the corresponding computations using S-PLUS. Work by Nelson [5] has been the definitive work on statistical models and methods for accelerated testing since it was published, while the work by Hahn and Shapiro [18] has been an important resource for statistical methods in engineering applications for many years. Yang [25] provides a broad overview of quantitative methods that should be used in processes

for the design of reliable systems from an engineering point of view. Crowder [9] provides a thorough treatment on the subject of competing risks models and subdistribution functions. These models are useful for modeling and prediction in reliability applications with multiple failure modes.

THE G/G/1 QUEUE

SERGEY FOSS
School of Mathematical and
Computer Sciences and
Maxwell Institute,
Heriot-Watt University,
Edinburgh, UK

The notation $G/G/1$ queue is usually referred to a single-server queue with first-in-first-out discipline and with a general distribution of the sequences of inter-arrival and service times (which are the “driving sequences” of the system). Customers are numbered $n = 0, 1, \dots$. We assume that customer 0 arrives at a system at time $t = 0$ and finds there an initial amount of work, so has to wait for $W_0 \geq 0$ units of time for the start of its service. Let t_n be the time between the arrivals of n th and $(n + 1)$ st customers, and s_n the service time of the n th customer. Let W_n be the waiting time (delay) of the n th customer, that is, the time between its arrival and beginning of its service. Then, for $n \geq 0$, the sequence $\{W_n\}$ satisfies *Lindley's equations*

$$W_{n+1} = (W_n + s_n - t_n)^+, \quad (1)$$

where we use the notation $x^+ = \max(0, x)$.

We assume the two-dimensional sequence $\{(s_n, t_n)\}$ to be stationary. We consider mostly the i.i.d. sequences ($GI/GI/1$ queue; here “ GI ” stands for “general independent”), and then the general case in brief. The list of references (Refs 1–13) contains a number of recent textbooks and surveys with the whole coverage of problems discussed in the article. The key references are Ref. 1 for the section titled “ $G/G/1$ queue,” and Refs 2 and 3 for the section titled “General $G/G/1$ queue.”

GI/GI/1 QUEUE

In this section we assume that each of the sequences $\{t_n\}$ and $\{s_n\}$ consists of i.i.d. (independent and identically distributed)

random variables (r.v.'s) and that these two sequences are independent and do not depend on W_0 . Without loss of generality, we may assume that these sequences are extended onto negative indices $n = -1, -2, \dots$. Let $T_0 = 0, T_n = \sum_{i=0}^{n-1} t_i, n \geq 1$, and $T_n = -\sum_{i=n}^{-1} t_i, n \leq -1$.

Let $a = \frac{1}{\lambda} = \mathbf{E}t_n \in (0, \infty)$ denote the Inter-arrival mean (expectation) and $b = \mathbf{E}s_n \in (0, \infty)$ the mean service time. Then $\rho = \lambda b$ is the *traffic intensity*. We consider the case of finite means only.

For the analysis of the waiting-time distributions, the key tool is the *duality* between the maximum of a random walk and the waiting time processes. Define $\xi_n = s_n - t_n$, $\mu = \mathbf{E}\xi_n = b - a, S_0 = 0, S_n = \xi_0 + \dots + \xi_{n-1}, M_n = \max_{0 \leq k \leq n} S_k$. Note that $\rho < 1$ and $\mu < 0$ are equivalent.

For the random walk $\{S_n\}$, the strong law of large numbers holds, $S_n/n \rightarrow \mu$ a.s. as $n \rightarrow \infty$. So, if $\mu < 0$, then the random variable $v = \max\{n : S_n > 0\}$ is finite a.s. and $M_n = M_v$ for all $n \geq v$. Then $M = \sup_{n \geq 0} M_n = M_v$ and, for any $n, \mathbf{P}(M_n \neq M) \leq \mathbf{P}(v > n) \rightarrow 0$, as $n \rightarrow \infty$.

Proposition 1. (1) For any $n \geq 0$, r.v.'s W_n and $\max(M_n, W_0 + S_n)$ are identically distributed,

$$W_n =_D \max(M_n, W_0 + S_n). \quad (2)$$

In particular, if $W_0 = 0$, then $W_n =_D M_n$ and probability $\mathbf{P}(W_n > x)$ increases in n , for any x .

(2) If $\rho < 1$, then a limiting steady-state waiting time W exists and coincides in distribution with that of $M, W =_D M$. Further, the distribution of W_n converges to that of W in the total variation norm, that is

$$\sup_A |\mathbf{P}(W_n \in A) - \mathbf{P}(W \in A)| \leq \mathbf{P}(v > n) \rightarrow 0, \quad n \rightarrow \infty. \quad (3)$$

For the steady-state random variable W and for an independent of it r.v. $\xi =_D \xi_1$, the random variables $(W + \xi)^+$ and W have the same distribution,

$$(W + \xi)^+ =_D W. \quad (4)$$

(3) If $\rho = 1$ and if $\sigma^2 = \mathbf{Var} \xi_n = \mathbf{Var} t_1 + \mathbf{Var} s_1$ is finite, then the distributions of $W_n/\sqrt{n}$ converge weakly, as $n \rightarrow \infty$, to the distribution of the absolute value of a normal random variable with mean 0 and variance σ^2 .

(4) If $\rho > 1$, then $W_n/n \rightarrow \mu$ a.s., as $n \rightarrow \infty$.

Regenerative Structure

Consider the case $W_0 = 0$. Let $\tau_0 = 0, \tau = \tau_1 = \inf\{n \geq 1 : W_n = 0\}$ and, for $k \geq 1$, $\tau_{k+1} = \inf\{n > \tau_k : W_n = 0\}$. Clearly, $\tau = \inf\{n \geq 1 : S_n \leq 0\}$.

Proposition 2. Assume $W_0 = 0$. If $\rho \leq 1$, then all τ_k are finite a.s. and the random elements $(\tau_k - \tau_{k-1}, (t_i, s_i, W_i), i = \tau_{k-1}, \dots, \tau_k - 1)$ are i.i.d. Moreover, if $\rho < 1$, then $\mathbf{E}\tau < \infty$ and, for any $\alpha > 1$, $\mathbf{E}\tau^\alpha < \infty$ if and only if $\mathbf{E}s_1^\alpha < \infty$. Further, if $\rho < 1$ and if $\mathbf{E}e^{c s_1}$ is finite for some $c > 0$, then $\mathbf{E}e^{c_1 \tau}$ is finite for some $c_1 > 0$.

We may interpret $\tau_k - \tau_{k-1}$ as the number of customers served in the k th busy period, the duration of the k th period is the total service time

$$B_k = \sum_{i=\tau_{k-1}}^{\tau_k-1} s_i,$$

and this busy period is followed by the *idle* period where the server is empty during

$$I_k = \sum_{i=\tau_{k-1}}^{\tau_k-1} t_i - \sum_{i=\tau_{k-1}}^{\tau_k-1} s_i = \sum_{i=\tau_{k-1}}^{\tau_k-1} (t_i - s_i)$$

units of time. The sum of a busy period and of the following idle period is a *busy cycle*, $C_k = B_k + I_k = \sum_{i=\tau_{k-1}}^{\tau_k-1} t_i$. In particular, the first idle period, I , is equal to $I = I_1 = -S_\tau$.

Proposition 3. Assume $W_0 = 0$. If $\rho < 1$, then $\mathbf{E}I$ is also finite and, for any function $f : [0, \infty) \rightarrow [0, \infty)$,

$$\mathbf{E}f((W + \xi)^-) = \frac{\mathbf{E}f(I)}{\mathbf{E}\tau} = -\mathbf{E}\xi \frac{\mathbf{E}f(I)}{\mathbf{E}I} \quad (5)$$

and, in particular,

$$\mathbf{E}(W + \xi)^- = -\mathbf{E}\xi. \quad (6)$$

Here we use notation $x^- = -\min(x, 0)$.

Moments of the Stationary Waiting Time

Proposition 4. Assume $\rho < 1$. Let W be the stationary waiting time. For any $\alpha > 0$, if $\mathbf{E}s_1^{\alpha+1} < \infty$, then $\mathbf{E}W^\alpha < \infty$. Conversely, if $\mathbf{E}W^\alpha < \infty$ and $\mathbf{E}t_1 < \infty$, then $\mathbf{E}s_1^{\alpha+1} < \infty$. Further, if, for some $k = 1, 2, \dots$, both $\mathbf{E}s_1^{k+1}$ and $\mathbf{E}t_1^{k+1}$ are finite, then

$$\begin{aligned} \sum_{l=0}^k C_{k+1}^l \mathbf{E}W^l \mathbf{E}\xi^{k+1-l} &= \mathbf{E}[-(W + \xi)^{k+1}] \\ &= (-1)^k \mathbf{E}\xi \frac{\mathbf{E}I^{k+1}}{\mathbf{E}I}. \end{aligned} \quad (7)$$

In particular,

$$\mathbf{E}W = \frac{\lambda^2(\mathbf{Var} t_1 + \mathbf{Var} s_1) + (1 - \rho)^2}{2\lambda(1 - \rho)} - \frac{\mathbf{E}I^2}{2\mathbf{E}I}, \quad (8)$$

and then

$$\begin{aligned} \frac{\rho^2 + \lambda^2 \mathbf{Var} s_1 - 2\rho}{2\lambda(1 - \rho)} &\leq \mathbf{E}W \\ &\leq \frac{\lambda(\mathbf{Var} t_1 + \mathbf{Var} s_1)}{2(1 - \rho)}. \end{aligned} \quad (9)$$

Here again, random variables W and $\xi = {}_D\xi_1$ are assumed to be independent.

Continuous Time. The Virtual Waiting Time

Recall that $C = C_1, B = B_1$, and $I = I_1$ are, correspondingly, the (duration of) the first busy cycle, the first busy period, and the first idle period.

Proposition 5. Assume $W_0 = 0$. Suppose $\rho < 1$. Then the busy cycle has mean $\mathbf{E}C = a\mathbf{E}\tau$, the busy period has mean $\mathbf{E}B = b\mathbf{E}\tau$, and the mean of the idle period is $\mathbf{E}I = \mathbf{E}C - \mathbf{E}B = -\mu\mathbf{E}\tau$.

Let $W(t)$ be the *virtual waiting time* at time t , that is, the total residual workload at

t , which is the sum of the residual service time of a customer in service and of all service times of customers in the queue. As a function of t , $W(t)$ decreases linearly between consecutive arrivals if positive and stays at zero if zero, with positive jumps at the arrival epochs. Further, $W_n = W(T_n -)$, $n = 0, 1, \dots$ and the process $W(t)$, $t \geq 0$ satisfied Lindley's equations in continuous time:

$$W(t) = (W(T_n -) + s_n - (t - T_n))^+, \quad t \in [T_n, T_{n+1}). \quad (10)$$

Non-Lattice Distribution. A random variable X has a non-lattice distribution if $\sum_{k=-\infty}^{\infty} \mathbf{P}(X = kh) < 1$, for all $h > 0$.

Proposition 6. Suppose that $\rho < 1$ and that $\{t_n\}$ have a common non-lattice distribution. Then there exists a limiting (stationary) distribution, as $t \rightarrow \infty$, of the virtual time $W(t)$ which is given by

$$\mathbf{P}(V > x) = \frac{1}{\mathbf{E}C} \mathbf{E} \left(\int_0^C \mathbf{I}(W(u) > x) du \right). \quad (11)$$

Further,

$$\mathbf{E}V = \rho \left(\frac{\mathbf{E}s^2}{2\mu_s} + \mathbf{E}W \right). \quad (12)$$

Here $\mathbf{I}(\cdot)$ is the indicator function, and $\mathbf{I}(A) = 1$ if event A occurs and $\mathbf{I}(A) = 0$ otherwise.

Proposition 7. Assume that a random variable $\hat{s}$ is independent of W and has an absolutely continuous distribution with density $\mathbf{P}(s > x)/b$ where $b = \mathbf{E}s_1$. Then

$$\mathbf{P}(V = 0) = 1 - \rho$$

and, for all $x \geq 0$,

$$\mathbf{P}(V > x) = \rho \mathbf{P}(W + \hat{s} > x).$$

Queue Length and Little's Law

We introduce three quantities: the queue length Q_n^A at the n arrival time, the queue length Q_n^D at the n departure time, and the queue length $Q(t)$ at an arbitrary time t .

Spread-Out Distribution. A probability distribution F is spread out if it can be represented as $F = pG_1 + (1-p)G_2$ where $p \in [0, 1)$, G_1 and G_2 are probability distributions, and G_2 is absolutely continuous with respect to Lebesgue measure.

Proposition 8. If $\rho < 1$, then the distribution of Q_n^A (correspondingly, of Q_n^D) converges, as $n \rightarrow \infty$, to that of a finite random variable Q^A (correspondingly, Q^D), in the total variation norm.

If $\rho < 1$ and the distribution of the inter-arrival times is non-lattice, then the distribution of $Q(t)$ converges weakly, as $t \rightarrow \infty$, to that of a finite random variable Q . If, in addition, the common distribution of inter-arrival times is spread out, then the convergence is in the total variation norm.

Proposition 9 [Little's Law]. Assume that $\rho < 1$, $\mathbf{E}s_1^2 < \infty$, and that the distribution of inter-arrival times is non-lattice. Then

$$q = \lambda(w + b), \quad (13)$$

where $q = \mathbf{E}Q$ is the mean stationary queue length, $\lambda = 1/a$ the arrival rate, and $w + b = \mathbf{E}(W + s_1)$ the mean stationary sojourn time, that is, the sum of mean waiting and mean service times.

Proposition 10 [Distributional Little's Law in Discrete Time]. Suppose $\rho < 1$. Then, for any $k = 1, 2, \dots$,

$$\begin{aligned} \mathbf{P}(Q^A \geq k) &= \mathbf{P}(Q^D \geq k) \\ &= \mathbf{P}\left(W + s_1 \geq \sum_{i=1}^k t_i\right), \end{aligned} \quad (14)$$

where the random variables W, s_1 , and $\{t_i\}_{i=1}^k$ are assumed to be mutually independent. Further, if either s_1 or t_1 has a continuous distribution, then Equations (14) are equivalent to

$$\mathbf{P}(Q^A = 0) = \mathbf{P}(Q^D = 0) = \mathbf{P}(W = 0). \quad (15)$$

and, for $k \geq 1$,

$$\mathbf{P}(Q^A \geq k) = \mathbf{P}(Q^D \geq k) = \mathbf{P}\left(W > \sum_{i=1}^{k-1} t_i\right). \quad (16)$$

Proposition 11 [Distributional Little's Law in Continuous Time]. Suppose that $\rho < 1$ and that the distribution of inter-arrival times is non-lattice. Then the stationary distribution of the queue length Q is given by

$$\mathbf{P}(Q = 0) = 1 - \rho$$

and, for $k = 1, 2, \dots$,

$$\begin{aligned} \mathbf{P}(Q \geq k) &= \mathbf{P}\left(V > \sum_{i=1}^{k-1} t_i\right) \\ &= \rho \mathbf{P}\left(W + \widehat{s} > \sum_{i=1}^{k-1} t_i\right), \end{aligned} \quad (17)$$

where we assume the mutual independence of all r.v.'s in the formula above.

Continuity Under Perturbation

Proposition 12. Consider a series of single-server queue indexed by the upper k . Assume that, as $k \rightarrow \infty$, the distributions of $t_1^{(k)}$ weakly converge to that of t_1 , the distributions of $s_1^{(k)}$ weakly converge to that of s_1 , and that $\rho < 1$ and $\rho^{(k)} < 1$, for all k . If $\mathbf{E}s_1^{(k)} \rightarrow \mathbf{E}s_1$, then the distributions of $W^{(k)}$ converge weakly to that of W . If, in addition, either the distribution of s_1 or the distribution of t_1 is continuous, then $\mathbf{P}(W^{(k)} = 0) \rightarrow \mathbf{P}(W = 0)$.

Heavy-Traffic Limits

Proposition 13. Consider a series of single-server queues indexed by the upper index k . Assume that, as $k \rightarrow \infty$, the distributions of $t_1^{(k)}$ weakly converge to that of t_1 , the distributions of $s_1^{(k)}$ weakly converge to that of s_1 , and that the distributions of s_1 and of t_1 do not both degenerate. Assume further that $\rho^{(k)} < 1$, for all k , and $\rho^{(k)} \rightarrow \rho = 1$, and that the squares $(s_1^{(k)})^2$ and $(t_1^{(k)})^2$ are uniformly integrable.

Then the distributions of random variables $Y^{(k)} = |\mu^{(k)}| W^{(k)} (\sigma^{(k)})^2$ converge weakly to an

exponential distribution with intensity 2 and also $\mathbf{E}Y^{(k)} \rightarrow \frac{1}{2}$. Furthermore, for each T and for $y \geq 0$,

$$\begin{aligned} &\mathbf{P}\left(\frac{|\mu^{(k)}|}{(\sigma^{(k)})^2} W^{(k)} \left[T(\sigma^{(k)})^2\right] > y\right) \\ &\rightarrow \mathbf{P}\left(\max_{0 \leq t \leq T} (B(t) - t) \geq y\right), \end{aligned} \quad (18)$$

where $\{B(t), t \geq 0\}$ is the standard Brownian motion, and $[x]$ is the integer part of a number x .

Rare Events

In the stable case, $\rho < 1$, the exact values of the tail probability $\mathbf{P}(W > x)$ may be found only in a number of particular cases. But the asymptotics for this probability may be written down in a great generality. There are two particular cases, of light tails and heavy tails, of the service time distributions, where the tail asymptotics differ and are caused by different phenomena.

For two positive functions f and g on the real line, we write $f(x) \sim g(x)$ if $\lim_{x \rightarrow \infty} \frac{f(x)}{g(x)} = 1$ as $x \rightarrow \infty$.

Rare Events in the Presence of Light Tails.

Proposition 14. Assume that $\rho < 1$ and the distribution of the service times has the light tail, $\mathbf{E}e^{ds_1} < \infty$ for some $d > 0$ and, moreover, that there exists a constant $\gamma > 0$ such that $\mathbf{E}e^{\gamma(s_1 - t_1)} = 1$ and $d := \mathbf{E}(s_1 - t_1)e^{\gamma(s_1 - t_1)} \in (0, \infty)$. Assume further that the distribution of r.v. $s_1 - t_1$ is non-lattice. Then, as $x \rightarrow \infty$,

$$\mathbf{P}(W > x) \sim re^{-\gamma x}, \quad (19)$$

where $r = \mathbf{E}e^{-\gamma \chi} \in (0, 1)$ and χ is the overshoot over the infinite barrier (see Refs 1 or 2 for the definition and more detail). Further, assume that $W = W_0$ is the stationary waiting time of customer 0 in the system that runs, say, from time $-\infty$. As $x \rightarrow \infty$,

$$\mathbf{P}(A(x) | W_0 > x) \rightarrow 1, \quad (20)$$

where $A(x)$ is the event of the form:

$$A(x) = \left\{ \begin{array}{l} \sum_{i=-\lfloor x/d \rfloor}^{-\lfloor x/d \rfloor + j - 1} (s_i - t_i) \\ \in (-R(x) + j(d - \varepsilon(x)), \\ R(x) + j(d + \varepsilon(x)), \\ \text{for } j = 1, 2, \dots, \lfloor x/d \rfloor \end{array} \right\},$$

and $R(x)$ is any function tending to infinity and $\varepsilon(x)$ is any function tending to zero, as $x \rightarrow \infty$. Roughly speaking, the latter means that, given the event $\{W_0 > x\}$ occurs, all increments $(s_i - t_i)$ are approximately equal to d , for $i = -\lfloor x/d \rfloor, -\lfloor x/d \rfloor + 1, \dots, -1$.

In particular, the distribution of $s_1 - t_1$ is non-lattice if either of the distributions of s_1 or t_1 is non-lattice.

Rare Events in the Presence of Heavy Tails.

Here we assume that the distribution of service times is *heavy-tailed*, that is, does not have finite exponential moments, $\mathbf{E}e^{\alpha s_1} = \infty$, for all $\alpha > 0$.

A distribution F on the positive half-line with an unbounded support is *subexponential* if

$$\overline{F * F}(x) \sim 2\overline{F}(x), \quad \text{as } x \rightarrow \infty.$$

It is known that any subexponential distribution is *long-tailed*, that is, $\overline{F}(x + c) \sim \overline{F}(x)$ as $x \rightarrow \infty$, for any constant c . Further, any long-tailed distribution is heavy tailed.

Typical examples of subexponential distributions are log-normal distributions, distributions with power tails $(1 + x)^{-\alpha}$, $\alpha > 0$, and Weibull tails e^{-x^β} , $\beta \in (0, 1)$.

Let again r.v. $\widehat{s}$ have the absolutely continuous distribution with distribution function $F_{\widehat{s}}(x)$ and density $f_{\widehat{s}}(x) = \mathbf{P}(s > x)/b$. Clearly, the distribution of service time s is heavy-tailed if and only if the distribution of $\widehat{s}$ is.

Proposition 15. *Assume that $\rho < 1$ and that the distribution of $\widehat{s}$ is subexponential.*

Then, as $x \rightarrow \infty$,

$$\begin{aligned} \mathbf{P}(W > x) &\sim \frac{\rho}{1 - \rho} (1 - F_{\widehat{s}}(x)) \\ &= \frac{1}{a - b} \int_x^\infty \mathbf{P}(s_1 > y) dy. \end{aligned} \quad (21)$$

Further, assume that $W = W_0$ is the stationary waiting time of customer 0 in the system that runs, say, from time $-\infty$. As $x \rightarrow \infty$,

$$\mathbf{P}(B(x) \mid W_0 > x) \rightarrow 1, \quad (22)$$

where $B(x)$ is the event of the form

$$B(x) = \bigcup_{i \geq 1} \{(s_{-i} > x + i(a - b))\}.$$

This means that, for large x , the main cause for the event $\{W_0 > x\}$ to occur is a single big jump of one of previous service times.

GENERAL G/G/1 QUEUE

In this subsection we consider the single-server queue under the stationary ergodic assumptions on the driving sequences. Namely, the sequence $\{(t_n, s_n)\}$ is *stationary* if the joint distribution of random vectors $\{(t_{m+i}, s_{m+i})\}_{0 \leq i \leq k}$ does not depend on m , for any k . In addition, this sequence is *ergodic* if, for any event A generated by the driving sequence, the equality $\mathbf{P}(A \cap A^\theta) = \mathbf{P}(A)$ implies that $\mathbf{P}(A)$ is either 0 or 1. Here A^θ is defined as follows: Any event A generated by the driving sequence may be represented as $A = \{g(t_i, s_i; i = \dots, -1, 0, 1, \dots) = 1\}$ where g is a measurable function of the driving sequence. Then $A^\theta = \{g(t_{i+1}, s_{i+1}; i = \dots, -1, 0, 1, \dots) = 1\}$. In particular, the sequence is ergodic if it is i.i.d. or, more generally, the tail sigma-algebra generated by this sequence is *trivial*, that is, contains only events of probability 0 or 1.

Proposition 16. *Under the stability condition $\rho = \mathbf{E}s_1/\mathbf{E}t_1 < 1$, there exists a unique stationary workload process $\widetilde{W}(t)$, $-\infty < t < \infty$ which satisfies Equations (10) on the whole real line and is such that*

$$\tilde{W}(0) = \sup_{n \leq 0} \left(T_n + \sum_{i=0}^n s_i \right)^+. \quad (23)$$

Further, there is an infinite number of negative indices n and infinite number of positive indices n such that $\tilde{W}(T_n-) = 0$.

If $\rho > 1$, then there is no finite stationary workload process and, for any initial condition $W_0 \geq 0$, $W(t)/t \rightarrow \rho - 1$ a.s., as $t \rightarrow \infty$.

If $\rho = 1$, then there may or may not exist a finite stationary process.

THE G/G/s QUEUE

LOTHAR BREUER
Institute of Mathematics and
Statistics, University of Kent,
Canterbury, UK

BASIC DEFINITIONS

The G/G/s queue features s servers, iid interarrival times, and iid service completion times. Arrival and service completion times are independent. Often this queue is denoted by GI/G/s in order to emphasize that the arrivals form a renewal process. We shall assume that $s > 1$ as the single-server case has been treated in the article titled *The G/G/1 Queue*. Unless stated otherwise, we further assume $s < \infty$. The most common service discipline considered is FCFS (first come first served), which we shall presume if nothing else is specified. We further assume, unless stated otherwise, that the servers are homogeneous, that is, all servers have the same distribution of service completion times. An arriving user will commence to be served immediately if at the time of arrival one of the servers is idle. Otherwise the user joins the queue at the back and will be served as soon as all users before they have commenced to be served and a server has become idle. The waiting room is infinite, unless specified otherwise.

The general G/G/s queue is of course the most difficult to analyze and a complete computationally tractable solution has not been derived yet. Functionals of interest are the number of users in the system (also called the *queue length*), the waiting times, the work load, or the length of a busy period. For the queue length, one may seek the transient distribution at a finite fixed time or the stationary distribution, which under some stability condition is attained asymptotically after the queueing system has run for a long time.

There is no mature general theory for the G/G/s queue. Results mostly concern special

aspects and employ methods quite diverse. Thus it is not possible to present a concise survey of the general multiserver queue. Indeed, most of the practically relevant questions still await a satisfying answer. We therefore present two classical results in the sections titled “The Markov Chain of Waiting Time Vectors” and “The G/M/s Queue,” while the last section contains a literature survey. This shall be roughly structured according to the functionals listed above. Although many results are included, this survey is by no means exhaustive.

THE MARKOV CHAIN OF WAITING TIME VECTORS

The construction of waiting time vectors gives rise to a (discrete-time) Markov chain analysis of the G/G/s queue, which has been initiated by the seminal paper [1]. The main results of this is shortly summarized in this section.

Let $t_0 := 0$ and denote the arrival time of the i th user by t_i , $i \in \mathbb{N}$, with $t_{i+1} \geq t_i$ for all $i \in \mathbb{N}$. The interarrival times shall be denoted by $g_i := t_i - t_{i-1}$, $i \in \mathbb{N}$. Let A denote the distribution function of the (iid) interarrival times. The service time of the i th user is denoted by R_i , $i \in \mathbb{N}$, and the distribution function of the (iid) service times R_i by H . Define $\rho := \mathbb{E}(H)/(s \cdot \mathbb{E}(A))$, where $\mathbb{E}(H)$ and $\mathbb{E}(A)$ denote the mean service and interarrival time, respectively.

We denote the waiting time of the i th user by w_i , $i \in \mathbb{N}$. This is the time duration between the arrival t_i of the i th user and the commencement of her service. Let $t_i + u_{ij}$ denote the time at which the j th server finishes serving the last of those among the $i - 1$ first users which it serves. For any real number $a \in \mathbb{R}$, define $a^+ := \max(0, a)$. Denote the order statistic by O , that is, $O(x_1, \dots, x_s) = (x_{(1)}, \dots, x_{(s)})$ is the permutation of $(x_1, \dots, x_s)$ such that $x_{(1)} \leq \dots \leq x_{(s)}$. Then the i th waiting time vector is defined as

$$w_i := (w_{i1}, \dots, w_{is}) := O(u_{i1}^+, \dots, u_{is}^+),$$

for all $i \in \mathbb{N}$. The iid nature of interarrival and service times entails that the sequence $(w_i : i \in \mathbb{N})$ is a Markov chain with $w_{i+1} = \phi(w_i, R_i, g_{i+1})$ for all $i \in \mathbb{N}$, where the function ϕ is defined by

$$\phi(w_i, R_i, g_{i+1}) := O((w_{i1} + R_i - g_{i+1})^+, (w_{i2} - g_{i+1})^+, \dots, (w_{is} - g_{i+1})^+). \quad (1)$$

Let $S := \{x = (x_1, \dots, x_s) \in \mathbb{R}^s : 0 \leq x_1 \leq x_2 \leq \dots \leq x_s\}$ denote the set of all ordered vectors with s nonnegative entries. Define the distribution functions

$$F_i(x|y) := \mathbb{P}(w_{i1} \leq x_1, \dots, w_{is} \leq x_s | w_1 = y),$$

for all $i \in \mathbb{N}$ and $x, y \in S$. Further define $F_i(x) := F_i(x|0)$, where 0 denotes the zero vector. The Markov property of $(w_i : i \in \mathbb{N})$ yields $F_{i+1}(x) = \int_{y \in S} F_i(x|y) dF_2(y)$ for all $i \in \mathbb{N}$ and $x \in S$. For $y_1, y_2 \in S$ with $y_1 \leq y_2$ (entry-wise) a sample path comparison yields $F_i(x|y_1) \geq F_i(x|y_2)$ for all $x \in S$ and $i \in \mathbb{N}$. Hence we obtain

$$F_{i+1}(x) - F_i(x) = \int_{y \in S} F_i(x|y) - F_i(x|0) dF_2(y) \leq 0,$$

which proves the inequality $F_{i+1}(x) \leq F_i(x)$ for all $i \in \mathbb{N}$ and $x \in S$. Thus the sequence $(F_i(x) : i \in \mathbb{N})$ approaches a limit $F(x)$ as $i \rightarrow \infty$. Let F denote the function on S with values $F(x)$. In Section 6 of Ref. 1, it is shown via discretisation of A and H and stochastic comparison arguments that F is a distribution function if $\rho < 1$. Under the opposite assumption $\rho \geq 1$ and $P(R_i = sg_i) < 1$, Section 7 therein shows that $\lim_{x' \rightarrow \infty} F(x', \dots, x') = 0$, that is, F is not a distribution function. The argument for this is a comparison to the G/G/1 queue with service times R_i and interarrival times $s \cdot g_i$.

Regarding ergodic properties of $(w_i : i \in \mathbb{N})$, we first observe that $F_i(x|y) \leq F_i(x) = F_i(x|0)$ for all $i \in \mathbb{N}$ and $x, y \in S$. Thus, $\lim_{i \rightarrow \infty} F_i(x|y) = 0$ for all $x, y \in S$ if $\rho \geq 1$ and $P(R_i = sg_i) < 1$. Assuming $\rho < 1$, Equation 8.1 in Ref. 1 states that $\lim_{i \rightarrow \infty} F_i(x|y) = F(x)$ for all $x, y \in S$, that is, F is the ergodic

distribution function of the Markov chain $(w_i : i \in \mathbb{N})$ which is independent of the initial value $w_1 = y$.

A fixed point equation for F can be derived as follows. Let P_i denote the probability measure on S that is determined by F_i . Recall definition (1) and define the set $\psi(x, b, c) := \{y \in S : \phi(y, b, c) \leq x\}$. Then $F_{i+1}(x) = \int P_i(\psi(x, b, c)) dH(b) dA(c)$ and $F_1(0) := 1$ provide a recursion for the distribution functions F_i . As $i \rightarrow \infty$, Lebesgue's theorem of dominated convergence allows to conclude

$$F(x) = \int P_\infty(\psi(x, b, c)) dH(b) dA(c), \quad (2)$$

where P_∞ denotes the measure determined by F . As the authors state, "it would be very desirable and interesting to solve the integral Equation (2), at least for interesting or important functions A and H . This, however, is likely to be very difficult."

THE G/M/s QUEUE

The most general special case that is solvable is the G/PH/s queue with phase-type service time distributions. Since PH distributions are dense within all distributions with positive support, the G/PH/s queue possibly might be regarded as an approximation of the G/G/s queue. Since a presentation of its solution is notationally rather extensive, we shall solve the more special case of the G/M/s queue instead. The solution has been derived in Ref. 2, while the following presentation is similar to Ref. 3 (Section 8.3). The solution of the G/PH/s queue follows along the same lines.

Assume that the interarrival times are iid with distribution function A , and every server has an exponential distribution with parameter $\mu > 0$. The service discipline is FCFS and the capacity of the waiting room is unbounded.

Since the exponential service time distribution is memoryless, the times of arrivals lead to an embedded Markov renewal chain. The system process $\mathcal{Q} = (Q_t : t \in \mathbb{R}_0^+)$ has state space $E = \mathbb{N}_0$, with Q_t indicating the number of users in the system (i.e., in service

or waiting) at time t . Define T_n as the time of the n th arrival and $X_n := Q_{T_n} - 1$ as the number of users in the system immediately before the n th arrival.

Clearly, the T_n are stopping times and X_n is a deterministic function of Q_{T_n} . We assume that A is not lattice, and $0 < \mathbb{E}(A) < \infty$. This implies, in particular, that $T_n \rightarrow \infty$ almost surely as n tends to infinity. The sequence $\mathcal{X} = (X_n : n \in \mathbb{N}_0)$ is a Markov chain since at times of arrivals the future of the system is determined only by the current number of users in the system, due to the memoryless property of the service times. The same property of the queue ensures

$$\begin{aligned} \mathbb{P}(Q_{T_n+t_1}=j_1, \dots, Q_{T_n+t_k}=j_k | Q_u \cdot u \leq T_n, X_n=i) \\ = \mathbb{P}(Q_{t_1}=j_1, \dots, Q_{t_k}=j_k | X_0=i). \end{aligned}$$

Thus the system process $\mathcal{Q}$ is Markov regenerative with embedded Markov renewal chain $(\mathcal{X}, \mathcal{T})$.

The transition probabilities p_{ij} of $\mathcal{X}$ are derived by the following considerations. Clearly, there may be only one arrival in any interval $[T_n, T_{n+1}]$. Hence $p_{ij} = 0$ for $j > i + 1$.

Now consider the case $j \leq i + 1 \leq s$. This means that during one interarrival period, no user is waiting and all are served with exponential intensity μ . Given that the interarrival period has length $t > 0$, the probability for any user to complete service is $1 - e^{-\mu t}$. A transition from state i to state j for the Markov chain $\mathcal{X}$ means that $i + 1 - j$ out of $i + 1$ users are served during one interarrival period. There are $\binom{i+1}{i+1-j} = \binom{i+1}{j}$ combinations to choose which users complete their service and which do not. Hence for $j \leq i + 1 \leq s$, we obtain

$$\begin{aligned} p_{ij} = \int_0^\infty \binom{i+1}{j} \\ \times (1 - e^{-\mu t})^{i+1-j} (e^{-\mu t})^j \, dA(t), \end{aligned}$$

by conditioning on the length t of the interarrival period.

The third case is $s \leq j \leq i + 1$. Here, all s servers are busy during the complete interarrival period. Then the number of

users served in time t is distributed like a Poisson process with intensity $s \cdot \mu$ evaluated at time t . Conditioning on the length of the interarrival period, we obtain

$$p_{ij} = \int_0^\infty \frac{(s\mu \cdot t)^{i+1-j}}{(i+1-j)!} e^{-s\mu t} \, dA(t), \quad (3)$$

for $s \leq j \leq i + 1$.

The last case to consider is $j < s < i + 1$. In this situation, there are $i + 1 - s$ users waiting in the queue at the beginning of the interarrival period, while $s - j$ servers are idle at the end of it. This is a mixture between the second and the third case. First the regime of the latter governs, until there are no waiting users any more (i.e., the queue has emptied). Then the former case applies. Thus, we condition first on the length t of the interarrival period and then on the time $u < t$ to empty the queue. The time to empty the queue has an Erlang distribution with $i + 1 - s$ stages and intensity $s\mu$. After that the number of served users has a binomial distribution with s degrees of freedom and parameter $p := e^{-\mu(t-u)}$. This leads to an expression

$$\begin{aligned} p_{ij} = \int_0^\infty \binom{s}{j} e^{-j\mu t} \int_0^t \frac{(s\mu u)^{i-s}}{(i-s)!} \\ \times (e^{-\mu u} - e^{-\mu t})^{s-j} s\mu \, du \, dA(t). \end{aligned}$$

Collecting these results, we can sketch the structure of the transition matrix as

$$P = \left(\begin{array}{ccc|ccc} p_{00} & p_{01} & & & & \\ p_{10} & p_{11} & p_{12} & & & \\ \vdots & & & \ddots & & \\ p_{s-2,0} & \dots & p_{s-2,s-1} & & & \\ p_{s-1,0} & \dots & p_{s-1,s-1} & \beta_0 & & \\ \hline p_{s,0} & \dots & p_{s,s-1} & \beta_1 & \beta_0 & \\ \vdots & & \vdots & \vdots & \ddots & \\ p_{s+n,0} & \dots & p_{s+n,s-1} & \beta_{s+1} & \beta_s & \dots & \beta_0 \\ \vdots & & \vdots & \vdots & \vdots & & \ddots \end{array} \right),$$

abbreviating $\beta_k := p_{i,i+1-k}$ in case (3). The nonspecified entries in P correspond to the case $j > i + 1$ and hence are zero. The matrix

P has an upper Hessenberg form. The most important part of it is the lower right-hand part containing the entries β_n . The other parts are boundary conditions.

In order to determine the stationary distribution of $\mathcal{X}$, we first consider the partition $E = F \cup F^c$ with $F = \{0, \dots, s-2\}$. We then obtain for the transition matrix P' of the Markov chain restricted to F^c the form

$$P' = \begin{pmatrix} r_0 & \beta_0 & & & \\ r_1 & \beta_1 & \beta_0 & & \\ r_2 & \beta_2 & \beta_1 & \beta_0 & \\ \vdots & \vdots & \ddots & \ddots & \ddots \end{pmatrix},$$

with $r_n = 1 - \sum_{k=0}^n \beta_k$. This has the same form as the respective transition matrix for the G/M/1 queue. Define $\rho = 1/(s\mu \cdot \mathbb{E}(A))$. The arguments for the G/M/1 queue all apply to the matrix P' with ρ defined as above. In the case $\rho < 1$, we obtain a stationary distribution $v' = v'P'$ given by

$$v'_n = (1 - \xi)\xi^n, \quad (4)$$

with $\xi = \sum_{n=0}^{\infty} \xi^n \beta_n$. For the case $\rho \geq 1$, it follows that P' (and hence P) is not positive recurrent.

In the following we assume $\rho < 1$. Then there is a unique extension of v' to a stationary measure for P , denoted by $v'' = v''P$. For this we have $v''_s = v'_{s-1}$ for all $n \geq s-1$ and $v''_{n+1} = \sum_{k=0}^{\infty} v''_k p_{k,n+1} = \sum_{k=n}^{\infty} v''_k p_{k,n+1}$ for all $n = 0, \dots, s-2$, which leads to

$$v''_n = \frac{1}{p_{n,n+1}} \times \left(v''_{n+1} \cdot (1 - p_{n+1,n+1}) - \sum_{k=n+2}^{\infty} v''_k p_{k,n+1} \right). \quad (5)$$

Thus v''_{s-2} and iteratively $v''_{s-3}, \dots, v''_0$ can be determined by formula (5). The stationary distribution $v = vP$ for $\mathcal{X}$ is then given as $v = c \cdot v''$ for a constant $c > 0$. This is determined by

$$c^{-1} = \sum_{n=0}^{\infty} v''_n = \sum_{n=0}^{s-2} v''_n + 1. \quad (6)$$

Altogether, formulae (4)–(6) yield the stationary distribution $v = vP$ for $\mathcal{X}$.

The asymptotic distribution of the queueing process Q is defined as the vector π on E with entries $\pi_n := \lim_{t \rightarrow \infty} \mathbb{P}(Q_t = n)$. This can now be obtained from the theory of Markov regenerative processes. For $n \geq s$, we obtain

$$\begin{aligned} \pi_n &= \frac{c}{\mathbb{E}(A)} \sum_{k=n-1}^{\infty} (1 - \xi)\xi^{k-(n-1)} \\ &\quad \times \int_0^{\infty} (1 - A(t))e^{-m\mu t} \frac{(m\mu t)^{k+1-n}}{(k+1-n)!} dt \\ &= \frac{c \cdot (1 - \xi)}{\mathbb{E}(A)} \int_0^{\infty} (1 - A(t))e^{-m\mu t} \xi^{n-m} \\ &\quad \times \sum_{k=n-1}^{\infty} \frac{(m\mu t \cdot \xi)^{k+1-n}}{(k+1-n)!} dt \\ &= \frac{c \cdot (1 - \xi)}{\mathbb{E}(A)} \xi^{n-m} \int_0^{\infty} (1 - A(t))e^{-m\mu t(1-\xi)} dt. \end{aligned}$$

Because of

$$\begin{aligned} \xi &= \sum_{n=0}^{\infty} \beta_n \xi^n = \int_0^{\infty} e^{-s\mu t} \sum_{n=0}^{\infty} \frac{(s\mu t \xi)^n}{n!} dA(t) \\ &= \int_0^{\infty} e^{-s\mu t(1-\xi)} dA(t) \end{aligned}$$

and integration by parts

$$\begin{aligned} &\int_0^{\infty} A(t)e^{-s\mu t(1-\xi)} dt \\ &= \frac{-1}{s\mu(1-\xi)} \left[A(t)e^{-s\mu t(1-\xi)} \right]_0^{\infty} - \frac{-1}{s\mu(1-\xi)} \\ &\quad \times \int_0^{\infty} e^{-s\mu t(1-\xi)} dA(t) \\ &= \frac{\xi}{s\mu(1-\xi)}. \end{aligned}$$

we obtain

$$\begin{aligned} &\int_0^{\infty} (1 - A(t))e^{-s\mu t(1-\xi)} dt \\ &= \int_0^{\infty} e^{-s\mu t(1-\xi)} dt - \int_0^{\infty} A(t)e^{-s\mu t(1-\xi)} dt \\ &= \frac{1}{s\mu(1-\xi)} - \frac{\xi}{s\mu(1-\xi)} = \frac{1}{s\mu}. \end{aligned}$$

Thus for $n \geq s$,

$$\pi_n = \rho \cdot c \cdot (1 - \xi) \xi^{n-m}.$$

Concerning the asymptotic probabilities π_n with $n = 1, \dots, s-1$, we employ the rate conservation law. We first give an intuitive explanation of this, an exact presentation can be found in Ref. 4 (Section VII.6). The arrival process of the G/M/s queue is a renewal process with renewal intervals distributed by A . Blackwell's theorem states that asymptotically an arrival occurs with constant rate $(\mathbb{E}(A))^{-1}$. Given that an arrival occurs, there is an asymptotic probability v_{n-1} of observing n users in the system. On the other hand, out of state $n \leq s-1$ (which has asymptotic probability π_n) the exponential servers provide a constant rate $n \cdot \mu$ to switch to state $n-1$. Now the rate conservation law states that asymptotically $v_{n-1}/\mathbb{E}(A) = \pi_n \cdot n\mu$, which means that the probability flow from state $n-1$ to state n equals the flow from n to $n-1$. This yields

$$\pi_n = \frac{v_{n-1}}{n\mu \cdot \mathbb{E}(A)},$$

for $n = 1, \dots, s-1$. Finally we obtain π_0 by normalization, that is,

$$\pi_0 = 1 - \sum_{n=1}^{\infty} \pi_n = 1 - \rho \cdot c - s\rho \sum_{n=1}^{s-1} \frac{v_{n-1}}{n}.$$

LITERATURE SURVEY

Waiting Times

General Results. Early results on work load and waiting time distributions can be found in Ref. 5. Here, the distribution of the actual waiting times is derived in terms of a solution of a set of integral equations. This approach has been extended in Ref. 6 and specified to (hyper)-exponential service times in Ref. 7. The stochastic chain of waiting times at the servers observed at the times that the users begin their service is analysed in Refs 1 and 8. It is shown there that an asymptotic (and hence stationary) distribution does exist if and only if $\rho < 1$. Harris

recurrence for this chain is investigated in Ref. 9. The work load vector as a process in continuous-time is analysed in Refs 10 and 11. This is generalized toward tandem queues with multiserver stations in Ref. 12.

It is shown in Ref. 13 that the working and the sojourn times of a user in a G/G/s queueing system are increasing and star-shaped with respect to the mean service time. Different service disciplines are compared in Refs 14 and 15. Some remarks on stochastic bounds for the delay distribution, commenting on Ref. 16, are given in Ref. 17.

Mean Stationary Waiting Time. Continuity of the mean stationary waiting time is proven in Ref. 18; see also Ref. 19. Bounds for this are derived in Refs 20 and 21, while conditions for it having finite moments are examined in Ref. 22. For further results on delay moments, see Refs 23–25. It is shown in Ref. 26 that the mean stationary waiting time is a convex and decreasing function of the number s of servers. This gives rise to a marginal benefit analysis for the optimal allocation of the number of servers; see also the earlier papers [27,28]. An example presented in Ref. 29 shows that even with bounded service times and an arbitrarily small traffic intensity, it may occur that the mean waiting time is infinite. Further results on the mean waiting time are given in Refs 30 and 31.

Asymptotic Results. Asymptotic growth of the maximum waiting time is analysed in Ref. 32. It is shown in Ref. 33, even for heterogeneous servers, that the waiting time is asymptotically exponential. Weaker logarithmic limits, assuming only positive Harris recurrence with no additional conditions, are derived in Ref. 34. The asymptotic behavior of the distribution tail of the stationary waiting time in the G/G/2 queue is studied in Ref. 35.

Approximations. An approximation of interarrival and service time distributions by mixed generalized Erlang distributions is analysed in Ref. 36. Some two-moment approximation formulas for the mean waiting time are proposed in Refs 37–41. It is, however, shown in Ref. 42 that any

approximation of the mean waiting time based only on the first two moments of the service time distribution must have an error with a strictly positive lower bound. Relations between the waiting time and the work load of an arbitrary server are derived in Ref. 43, where further bounds and approximations for the mean waiting time can be found.

Work Load

Existence and uniqueness of the stationary distribution of the work load at arrival times is shown in Ref. 1, for generalizations, see Refs 44–46. An alternative proof for uniqueness is given in Ref. 47. An expression for the total work load in the system is given in Ref. 43. A lower bound in terms of a related G/G/1 queue is given in Ref. 4 (Chapter 12). Sample-path inequalities regarding cyclical assignment of servers are derived in Ref. 48. Optimality of the FCFS service discipline in terms of remaining work load is shown in Refs 49–51. Asymptotics for the distribution tail of the stationary two-dimensional work load vector in the G/G/2 queue are derived in Ref. 35. Further results can be found in Refs 52 and 53.

Queue Length

General Results. The earliest papers [54–56] on the number of users in the system treat the special case M/M/s (see *The M/M/s Queue*), while the G/M/s queue is analyzed in Ref. 2. It is shown in Ref. 1 that for $\rho \geq 1$, there is no stationary distribution of the queue length, except in the trivial case of $\mathbb{P}(S = sT) = 1$. For the case of atomless interarrival and service time distributions, it is shown in Ref. 57 that the queue length converges in distribution as time passes. An implicit equation for the transient distribution is given in Ref. 58.

Stationary Distribution. It is shown in Ref. 59 that the stationary distributions at arbitrary points in time and at arrival or departure epochs are comparable with respect to the stochastic order relation. In Ref. 60, it is shown that the stationary distribution has an operator-geometric form if the interarrival

times are absolutely continuous. More results on the steady-state distribution can be found in Ref. 61. The distribution of the number of busy servers is studied in Ref. 62. Some results on the stationary probability that all servers are busy can be found in Refs 63 and 64.

Approximations and Asymptotic Results.

An approximation of interarrival and service time distributions by Coxian distributions is analysed in Ref. 65. A diffusion approximation for the stationary queue length is developed in Ref. 66; see also Ref. 67.

Asymptotic growth of the maximum queue length is analysed in Ref. 32. It is shown in Ref. 33, even for heterogeneous servers, that the queue length is asymptotically geometric. Asymptotics for the distribution tail of the queue length in the G/G/2 queue are derived in Ref. 35.

Busy Period

A conventional busy period begins when an arrival finds all servers idle and ends when, for the first time after that, a departure leaves the system empty. Finiteness of ϕ -moments for a busy period is investigated in Ref. 68. It is proved in Ref. 69 that in a GI/G/s queue with a traffic intensity $\rho < (s - m + 1)/s$, $m \geq 1$, at least m servers are simultaneously idle infinitely often with probability 1. The special case $m = s$ is treated in Ref. 70.

A slightly different concept, introduced in Ref. 71, is the full busy period: It begins when an arrival finds $s - 1$ users in the system, that is, exactly one server is idle, and ends when, for the first time after that, a departure leaves behind $s - 1$ users in the system. Conditions for the full busy period to have finite moments are derived in Ref. 72, the same for the related virtual work in Ref. 73. The distribution of the remaining time in a full busy period starting from a random epoch is given in Ref. 74.

Model Fitting

Given a sample path of the queue length process, conditions for identifiability of the interarrival and service time distributions are derived in Ref. 75. On the basis of the output epochs of a G/G/ ∞ queue, Ref. 76

provides a related result. A cross-spectral analysis of the G/G/ ∞ queue is performed in Ref. 77. A large sample test based on a normal approximation for the traffic intensity parameter ρ is proposed in Ref. 78.

Heavy Traffic

Under the assumption of heavy traffic (i.e., here $\rho > 1$), central limit theorems for the queue length process are derived in Refs 79 and 80. The analysis is based on Ref. 81. In Ref. 82, the limit as the arrival rate and the number s of servers jointly tend to infinity is investigated; see also Ref. 83. A diffusion approximation based on the first two moments of interarrival and service times is proposed in Ref. 84. Convergence theorems for the waiting time are derived in Ref. 85. An exponential limiting formula for the waiting time distribution is established in Ref. 86; see also Ref. 87 for further properties.

Special Cases

Approximations for specific PH/G/s queues are given in Ref. 88. A diffusion approximation for the G/G/s queue with group arrivals is given in Ref. 89. In the case of a LCFS service discipline, conditions for finite mean waiting times are derived in Ref. 29.

Finite Capacity Queues and Loss Systems. A diffusion approximation for the G/G/s/m finite capacity queue is proposed in Ref. 90. More results on the finite capacity case can be found in Ref. 91.

The rate of convergence to a steady-state in the G/G/s loss system is investigated in Ref. 92. The asymptotic performance of a G/G/s loss system with heterogeneous servers and retrials is analysed in Ref. 93. Some effects of the deletion of arrivals on the G/G/s loss system are investigated in Ref. 94.

Priority Classes. A conservation law for the G/G/s queue with priority classes has been proved in Ref. 95. An approximation of the mean response times in a G/G/s queue with priority classes and preemptive resume service discipline is proposed in Ref. 96. Waiting and sojourn times in a G/M/s queue with mixed priorities are determined in Ref. 97.

The G/G/ ∞ Queue. The infinite server case $s = \infty$ is clearly much simpler to analyze, as there are no waiting users. Existence of steady-state distributions for the number of users and the work load vector is proven in Ref. 98. Steady-state results for the number of users in the system are derived in Ref. 99. Results on the busy period are given in Ref. 100. The transient distribution of the number of users in the system and of the total work load is examined in Ref. 101. For approximations, see Ref. 102.

The G/PH/s Queue. It has been shown in Ref. 103 that the distribution of the stationary waiting time is phase-type. Its representation is derived in Ref. 104 in a form which is explicit up to the solution of a matrix fixed point problem. A Wiener–Hopf factorisation is developed in Ref. 105. An algorithmic solution to the stationary distribution of the number of users in the system is presented in Ref. 106 (Section 4.5). Efficient algorithms for its computation are given in Ref. 107.

THE $G/M/1$ QUEUE

DAVID PERRY
Department of Statistics,
University of Haifa,
Haifa, Israel

INTRODUCTION

This article constitutes a natural continuation of the article titled *The $M/G/1$ Queue* in this encyclopedia, that is focused on the $M/G/1$ queue. Accordingly, the $G/M/1$ queue is characterized as a single server queue with exponentially distributed (μ) service times which are independent of each other and of the arrival process in which the successive interarrival times are independent and identically distributed (iid) random variables. Let G denote the interarrival time distribution, with $G^*(\alpha)$ being the Laplace Stieltjes transform (LST) and $\lambda = -\frac{dG^*(\alpha)}{d\alpha}|_{\alpha=0}$ denoting the arrival rate. We proceed according to the concept of duality between the $G/M/1$ and the $M/G/1$ queues; this argument says that in order to realize the $G/M/1$ queue one can use the same set of random variables as those used for the $M/G/1$ queue, but under the modification that the interarrival times and the services are reversed. This means that in the dual $M/G/1$ queue, the arrival process is Poisson with rate μ and G is the service distribution. We designate $\rho := \mu/\lambda$. Then, the *traffic intensity* of the primal $M/G/1$ queue is ρ , but for the dual $G/M/1$ queue it is ρ^{-1} . Treatments of the $G/M/1$ queue may be found in several books on queueing theory [1–7].

For later use, we start by citing two limit theorems about irreducible aperiodic discrete-time Markov chain on a countable state space. Theorems 1 and 2 below enable us to classify the states of the chain into one out of three classes of equivalence: either all states are positive recurrent, null recurrent, or transient. Accordingly, in

Theorem 1 below we introduce a necessary and sufficient condition for the chain to be ergodic (which means that any set of states is positive recurrent). In particular, if the chain is not ergodic, then all states are either null recurrent or transient. In the nonergodic case, we give in Theorem 1 a necessary and sufficient condition for all states to be recurrent. Then, in Theorem 2 below we introduce a necessary and sufficient condition for all states to be recurrent (which implies that all states must be null recurrent).

It turns out that the embedded processes of the number of customers just after departures in the $M/G/1$ queue and the number of customers just before arrivals in the $G/M/1$ queue, respectively, are irreducible aperiodic discrete-time Markov chains with state space $E = \{0, 1, 2, \dots\}$. In the section titled “Duality,” we apply Theorems 1 and 2 to the duality between the $M/G/1$ and the $G/M/1$ queues. As will be seen, with ρ fixed, when the $M/G/1$ system is positive recurrent the $G/M/1$ system is transient and vice versa. When the $G/M/1$ system is null recurrent the $M/G/1$ system is also null recurrent.

In the sequel, we restrict the attention to the stable case of the $G/M/1$ queue (the case $\rho > 1$). We focus on the main factors of interest: limiting number of customers seen by arbitrary arrivals, waiting times and sojourn times in steady state, and busy periods and idle periods.

Remark 1. The $G/M/1$ system is a less natural model than the $M/G/1$ since, in practice, services are rarely exponential because of the memoryless property. However, as will be seen, the *attained waiting time* (AWT) process (which is the reversed version of the *work* process) of the $G/M/1$ queue can also be interpreted as the content level of an insurance risk cash fund with Poisson(μ) arrivals and generally distributed claims. Then, in the case of $\rho > 1$, the $G/M/1$ queueing system is stable, but for the insurance risk interpretation a ruin (bankruptcy), somewhere in the future, is a certain event (the latter statement

is also valid for the case of $\rho = 1$). In the case of $\rho < 1$, the $G/M/1$ queueing system is unstable, and under the insurance risk interpretation, no matter what the initial state is, a ruin is not a sure event.

TWO LIMIT THEOREMS

We introduce two well-known limit theorems that can be found in many introductory books about Markov chains (therefore, the proofs are omitted here; see Theorem 2.1, p. 152 and Theorem 5.34, p. 176 in Çinlar [8]). The relevance of the two theorems to the $M/G/1$ and the $G/M/1$ queues stems from the fact that the number of customers left behind a departing customer in the $M/G/1$ queue and the number of customers seen at the moment of arrival in the $G/M/1$ queue are irreducible aperiodic Markov chains.

Let $\mathbf{X}$ be an arbitrary irreducible aperiodic Markov chain with state space $E = \{0, 1, 2, \dots\}$ and transition matrix $\mathbf{P} := \|p(i, j)\|$.

Theorem 1. *All states are positive recurrent if and only if the system of linear equations*

$$\begin{aligned} \pi &= \pi \mathbf{P} \\ \text{and} \\ \pi \mathbf{1} &= 1 \end{aligned}$$

has a solution π . If there exists a solution π then it is strictly positive, there are no other solutions, and we have

$$\pi_j = \lim_{n \rightarrow \infty} p^n(i, j),$$

for all $i, j \in E$.

Before introducing the second theorem, we mention that if there are infinitely many states, it is possible that all of them are transient. Then, it is possible for the chain to remain in the set of transient states forever. Practically speaking, let A be a subset of the state space E , and let $\mathbf{Q} := \|Q(i, j)\|$ be the matrix obtained from $\mathbf{P}$ by deleting all the rows and columns corresponding to the states which are not in A . Then,

$$\begin{aligned} \sum_{j \in A} Q^n(i, j) &= \Pr(X_1 \in A, \dots, X_n \in A \mid X_0 = i), \\ i &\in A. \end{aligned} \quad (1)$$

Clearly, the number in Equation (1) decreases as n increases. Let

$$f(i) = \lim_{n \rightarrow \infty} \sum_{j \in A} Q^n(i, j), \quad i \in A;$$

in words, $f(i)$ is the probability that starting at $i \in A$, the chain stays in the set A forever. Then, for its computation of $f(i)$ we have the following.

Theorem 2. *The function f is the maximal solution of the system of linear equations*

$$\mathbf{h} = \mathbf{Q}\mathbf{h}, \quad 0 \leq \mathbf{h} \leq 1.$$

Either $f = 0$ or $\sup_{i \in A} f(i) = 1$.

It was already mentioned that the special duality between the $G/M/1$ queue and the $M/G/1$ queue is achieved by reversing the roles of the interarrival times and the service times. As will be seen, when $\rho > 1$ the $M/G/1$ queue size is likely to increase to infinity, but in the $G/M/1$ queue the server can keep up with arrivals and we expect the queue sizes to be positive recurrent; if $\rho < 1$ then the $G/M/1$ system is transient and the $M/G/1$ queue is positive recurrent; in the case of $\rho = 1$ both the $G/M/1$ queue and the $M/G/1$ queue are null recurrent. Obviously, when the embedded $M/G/1$ and $G/M/1$ processes are positive recurrent, null recurrent, or transient, the continuous-time processes are also positive recurrent, null recurrent, or transient, respectively.

DUALITY

The mentioned duality extends somewhat further; in the case of positive recurrence, it enables to obtain the limiting law of the queue size seen by an arriving customer in the $G/M/1$ system as a function of the probabilities of never becoming empty in the $M/G/1$ system. To see this, let X_n^* be the number of customers in the $M/G/1$

system after the instant of the n th departure. It follows from the article titled **The M/G/1 Queue** in this encyclopedia that $\mathbf{X}^* = \{X_k^* : k = 1, 2, \dots\}$ is an irreducible aperiodic Markov chain with state space $E = \{0, 1, \dots\}$ and transition matrix

$$\mathbf{P}^* = \begin{bmatrix} q_0 & q_1 & q_2 & q_3 & \cdot & \cdot \\ q_0 & q_1 & q_2 & q_3 & \cdot & \cdot \\ 0 & q_0 & q_1 & q_2 & \cdot & \cdot \\ 0 & 0 & q_0 & q_1 & q_2 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix}, \quad (2)$$

where

$$q_n = \int_0^\infty \frac{e^{-\mu t} (\mu t)^n}{n!} dG(t) \quad (3)$$

is the probability for exactly n arrivals within an arbitrary service.

To show that the chain $\mathbf{X}^*$ is positive recurrent and aperiodic, one has to apply Theorem 1 and solve the set of linear equations

$$\begin{aligned} \pi^* &= \pi^* \mathbf{P}^* \\ \text{and} \\ \pi^* \mathbf{1} &= \mathbf{1}. \end{aligned}$$

It follows from Theorem 1 that the solution of π exists if and only if $\rho < 1$ and is given by its generating function

$$\Pi^*(z) = \frac{(1 - \rho)(1 - z)G^*(\lambda(1 - z))}{G^*(\lambda(1 - z)) - z}, \quad (4)$$

where G^* is the LST of the service time distribution (see **The M/G/1 Queue**).

Remark 2. When restricting attention to the case of positive recurrence it should be noted that, in the M/G/1 queue, the number of customers left behind a departing customer and the number of customers in steady state are stochastically equal by ASTA [9], so that Equation (4) is also the generating function of the number of customers in steady state. However, the number of customers seen by an arriving customer and the number of customers in steady state in the G/M/1 queue are not necessarily stochastically equal.

Theorem 3 below is of crucial importance for the condition of stability for the G/M/1

queue, although it is applied to the M/G/1 queue. Based on Theorems 1 and 2 above, Theorem 3 shows that the chain $\mathbf{X}^*$ (the embedded chain just after the moments of departures in the M/G/1 queue) is recurrent non-null if and only if $\rho < 1$, null recurrent if and only if $\rho = 1$, and transient if and only if $\rho > 1$. To prove the latter statement, we interpret $f(j)$ as the probability that the M/G/1 queue, starting with j customers, never becomes empty.

Theorem 3. We have

$$f(j) = 1 - \beta^j, \quad j = 1, 2, \dots, \quad (5)$$

where β is the smallest number in $[0, 1]$ satisfying

$$\beta = q_0 + q_1\beta + q_2\beta^2 + \dots \quad (6)$$

Proof. We observe from the shape of the transition matrix $\mathbf{P}^*$ in Equation (2) that starting from $j + 1$, in order for the queue to become empty, $\mathbf{X}^*$ must first reach j . Therefore, starting from $j + 1$, the queue can avoid becoming empty either by never reaching j or, if it does reach j , by never becoming empty starting from j . Since the probability of never reaching j starting with $j + 1$ customers is the same for all j , it is equal to $f(1)$. Thus, we get

$$f(j + 1) = f(1) + [1 - f(1)]f(j), \quad j = 1, 2, \dots$$

Assigning $f(1) = 1 - \beta$ and solving this recursively, we obtain Equation (5). It remains to compute β . From Theorem 2, f is the maximal solution of $\mathbf{h} = \mathbf{Q}^*\mathbf{h}$, $0 \leq \mathbf{h} \leq \mathbf{1}$, with $\mathbf{Q}^*$ given by

$$\mathbf{Q}^* = \begin{bmatrix} q_1 & q_2 & q_3 & \cdot & \cdot \\ q_0 & q_1 & q_2 & \cdot & \cdot \\ 0 & q_0 & q_1 & q_2 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix}. \quad (7)$$

From the first equation of $\mathbf{h} = \mathbf{Q}^*\mathbf{h}$ we see that f must satisfy

$$f(1) = q_1f(1) + q_2f(2) + \dots,$$

which, upon using the values in Equation (5), implies that β satisfies Equation (6). Since f

is the maximal such solution, β must be the smallest possible solution of Equation (6). We need to show that $\beta < 1$ (and therefore that $f \neq 0$, which in turn implies that $\mathbf{X}^*$ is transient) if and only if $\rho > 1$. Consider the function

$$K(\beta) = q_0 + q_1\beta + q_2\beta^2 + \dots, \quad 0 \leq \beta \leq 1.$$

Clearly, $K(\beta)$ is nonnegative, increasing, and has an increasing derivative. This implies that $K(\beta)$ can intersect the line $H : H(\beta) = \beta$ at most once in $(0, 1)$ (of course, they always intersect at $\beta = 1$). Consider the derivative $K'(\beta)$ at $\beta = 1$. If $K'(1) > 1$, the point of intersection β is strictly less than 1; otherwise, if $K'(1) \leq 1$, then K and H have no point of intersection in $(0, 1)$, and the smallest number β with the desired properties is 1. Finally, note that $K'(1) = \rho$.

Now consider the G/M/1 queue and denote the number of customers in the system by X_n , just before the time T_n of the n th arrival. We introduce the notation $r_n = q_{n+1} + q_{n+2} + \dots$. Here q_n is interpreted as the probability that the server completes exactly n services during an interarrival time provided that there are sufficiently many customers available to be served. Obviously,

$$\rho = \sum_{n=1}^{\infty} nq_n = r_0 + r_1 + \dots = \mu/\lambda$$

is the expected number of services that the server is capable of completing during an interarrival time.

Claim 1. $\mathbf{X} = \{X_n : n = 1, 2, \dots\}$ is a Markov chain with state space $E = \{0, 1, \dots\}$ and transition matrix $\mathbf{P} := \|p(i, j)\|$ given by

$$\mathbf{P} = \begin{bmatrix} r_0 & q_0 & & & 0 \\ r_1 & q_1 & q_0 & & \\ r_2 & q_2 & q_1 & q_0 & \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix}. \quad (8)$$

To validate Claim 1 let M_{n+1} be the number of services completed during the $(n+1)$ th interarrival time $[T_n, T_{n+1})$. Then,

$$X_{n+1} = X_n + 1 - M_{n+1}. \quad (9)$$

In other words, X_{n+1} is the number of customers that were in the system before the n th arrival plus the n th customer and less those whose services were completed during the $(n+1)$ th interarrival time. From Equation (9) it follows that $\mathbf{X}$ is a Markov chain only if M_{n+1} is conditionally independent of the past history before T_n given the present number X_n . But the latter statement is obvious because of the independence of the service times and the interarrival times, and the fact that, by the memoryless property of the exponential distribution, the remaining service time of the customer who is being served at time T_n (if any) has the same exponential distribution as any service time. The above reasoning shows that as long as there are customers to be served, the conditional distribution of the number of services completed is Poisson: with $Z = T_{n+1} - T_n$,

$$\begin{aligned} \Pr[M_{n+1} = k \mid X_n, Z] \\ = \begin{cases} \frac{e^{-\lambda Z} (\lambda Z)^k}{k!} & \text{if } X_n + 1 > k \\ \sum_{m=k}^{\infty} \frac{e^{-\lambda Z} (\lambda Z)^m}{m!} & \text{if } X_n + 1 = k \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

Taking expectation with respect to Z , which is independent of X_n , we obtain

$$\begin{aligned} \Pr[M_{n+1} = k \mid X_n = i] \\ = \begin{cases} q_k & \text{if } k \leq i \\ r_{k-1} & \text{if } k = i + 1 \\ 0 & \text{otherwise.} \end{cases} \quad (10) \end{aligned}$$

Combining Equations (9) and (10), we see that the transition probabilities $p(i, j)$ are as claimed.

It is clear from an inspection of Equation (8) that the Markov chain $\mathbf{X}$ is irreducible and aperiodic. Therefore, all the states are of the same class of equivalence [8, Chapter 5; Theorem 3.16]. The proof of the next theorem is based on the duality between the G/M/1 queue and the M/G/1 queue; we show that the Markov chain $\mathbf{X}$ is positive recurrent if and only if $\rho > 1$.

Theorem 5. $\mathbf{X}$ is positive recurrent if and only if $\rho > 1$. If $\rho > 1$, the limiting distribution

$$\pi_j = \lim_{n \rightarrow \infty} \Pr(X_n = j \mid X_0 = i)$$

is given by

$$\pi_j = (1 - \beta)\beta^j, \quad j = 0, 1, 2, \dots,$$

where β is given in Equation (6). If $\rho \leq 1$, then $\pi_j = 0$ for all j .

Proof. According to Theorem 1, $\mathbf{X}$ is positive recurrent if and only if $\pi = \pi \mathbf{P}$, $\pi \mathbf{1} = \mathbf{1}$ has a solution. Writing out the equations, with $r_n = q_{n+1} + q_{n+2} + \dots$, we have

$$\begin{aligned} \pi_0 &= q_1\pi_0 + q_2\pi_0 + q_3\pi_0 + \dots \\ &\quad + q_2\pi_1 + q_3\pi_1 + \dots \\ \pi_1 &= q_0\pi_0 + q_1\pi_1 + q_2\pi_2 + \dots \\ \pi_2 &= q_0\pi_1 + q_1\pi_2 + q_2\pi_3 + \dots \\ &\vdots \end{aligned} \quad (11)$$

Let a function f be defined by

$$f(j) = \pi_0 + \pi_1 + \dots + \pi_{j-1}, \quad j = 1, 2, \dots \quad (12)$$

The equation for π_0 gives an equation for $f(1)$, summing the equations for π_0 and π_1 yields an equation for $f(2)$, and so on. We obtain

$$\begin{aligned} f(1) &= q_1f(1) + q_2f(2) + q_3f(3) + \dots, \\ f(2) &= q_0f(1) + q_1f(2) + q_2f(3) + \dots, \\ f(3) &= q_0f(2) + q_1f(3) + \dots, \end{aligned}$$

so that f satisfies

$$\mathbf{f} = \mathbf{Q}^* \mathbf{f}, \quad (13)$$

where $\mathbf{Q}^*$ is given in Equation (7). In other words, $\mathbf{Q}^*$ is the matrix obtained from $\mathbf{P}^*$ in Equation (2) by deleting the first row and the first column (corresponding to state $\{0\}$).

We are interested in the solution of Equation (13) satisfying

$$\lim_{j \rightarrow \infty} f(j) = \sum_{j=0}^{\infty} \pi_j.$$

We conclude (see Proposition 4.5, p. 167 of Çinlar [8]) that such a solution exists if and only if the chain $\mathbf{X}$ is transient. By Theorem 3, this is true if and only if $\rho > 1$. If $\rho > 1$, the solution for f is given by Equation (5), where β satisfies Equation (6). Solving for π in Equation (11) by using Equations (12) and (5) for f , we obtain

$$\begin{aligned} \pi_0 &= f(1) = 1 - \beta, \\ \pi_1 &= f(2) - f(1) = (1 - \beta)\beta, \\ &\vdots \end{aligned}$$

which is the same as the claimed limiting distribution π in Theorem 4. Finally, the statement that $\rho \leq 1$ implies that $\pi = \mathbf{0}$ follows again from the duality between the M/G/1 and the G/M/1 queues.

Next we restrict the attention to the case of $\rho > 1$ and focus on other relevant measures of the G/M/1 queue.

WORK AND ATTAINED WAITING TIME

In addition to the duality argument above, several derivations in this review are based on sample-path analysis of two dual compound processes; the so-called *work process* (or *workload process*), sometimes called the *virtual waiting time* (VWT) and the *Attained waiting time* (AWT) processes. The times between successive arrivals are iid random variables $S_1, S_2, \dots$, and the service requirements of arriving customers are iid random variables $Z_1, Z_2, \dots$.

Let $\mathbf{N} = \{N(t) : t \geq 0\}$ and $\mathbf{\Lambda} = \{\Lambda(t) : t \geq 0\}$ be counting processes such that for all $t \geq 0$, $n = 0, 1, \dots$ and $m = 0, 1, \dots$, $\{N(t) \geq n\} = \{Z_1 + \dots + Z_n \leq t\}$ and $\{\Lambda(t) \geq m\} = \{S_1 + \dots + S_m \leq t\}$. Obviously, $\mathbf{N}$ is a Poisson process with rate μ , and $\mathbf{\Lambda}$ is a renewal process whose inter-renewal distribution is $G(\cdot)$ with mean $1/\lambda$. Now define the continuous-time random walks $\mathbf{X} = \{X(t) : t \geq 0\}$ where $X(t) = t - (S_1 + \dots + S_{N(t)})$

and $\mathbf{Y} = \{Y(t) : t \geq 0\}$ where $Y(t) = (Z_1 + \dots + Z_{\Lambda(t)}) - t$. Then, construct the reflected processes $\mathbf{A} = \{A(t) : t \geq 0\}$ and $\mathbf{V} = \{V(t) : t \geq 0\}$, by $A(t) = X(t) - \inf_{0 \leq s \leq t} X(s)$ and $V(t) = Y(t) - \inf_{0 \leq s \leq t} Y(s)$. Here $\mathbf{A}$ is interpreted as the conditional AWT process of the G/M/1 queue in which the idle periods are deleted and the busy periods are glued together. The process $\mathbf{V}$ is interpreted as the VWT process (or the work process) of the same G/M/1 queue.

The processes $\mathbf{V}$ and $\mathbf{A}$ are dual processes with respect to waiting times. While $V(t)$ is interpreted as the time that a customer would have to wait in line if he arrived at t , $A(t)$ is interpreted as the conditional time (given it is strictly positive) already attained (or elapsed) since the arrival of the customer, who is being served at t . In other words, while $\mathbf{V}$ designates the waiting time of a virtual customer by looking forward in time (the customer is virtual in the sense that he did not arrive at t and thus, in practice, he contributed nothing to the work), $\mathbf{A}$ designates the conditional waiting time of a real customer (given it is strictly positive) by looking backward in time. As a result, while the VWT might sometimes be equal to 0, the conditional AWT cannot be 0 because the served customer “sees” at least himself in the system. By that interpretation, the steady-state law of $\mathbf{A}$ and that of $\mathbf{V}$ must be closely related to each other. In fact, it can be shown by construction [10] that the steady-state law of $\mathbf{A}$ is equal to the conditional steady-state law of $\mathbf{V}$, given that the idle periods (the time periods in which $V = 0$) are deleted and the busy periods are glued together. Note that $\rho > 1$ implies that both $\mathbf{X}$ and $\mathbf{Y}$ tend to $-\infty$ a.s., so that $\mathbf{A}$ and $\mathbf{V}$ are regenerative processes. Furthermore, the cycles associated with $\mathbf{A}$ are the busy periods and those associated with $\mathbf{V}$ are the busy cycles (the busy cycle is composed of busy period plus idle period). Also, it can be shown [10] that the stopping times $T = \inf\{t \geq 0 : X(t) \leq 0\}$ and $\tau = \inf\{t \geq 0 : Y(t) = 0\}$ are the same random variables that represent the busy period of the G/M/1 queue.

Note that a busy cycle generated by $\mathbf{V}$ is $C = \inf\{t \geq \tau : V(t) > 0\}$. Thus, $C - T$ and

$-A(T)$ are the same random variables representing the idle period. Also, while the sample path of $\mathbf{V}$ is continuous at τ and $V(\tau-) = V(\tau+) = 0$, $A(T)$ is a point of discontinuity since, by definition, $A(T-) > 0 > A(T)$.

WAITING TIMES AND SOJOURN TIMES

We first study the AWT process $\mathbf{A}$, showing that its steady-state distribution is exponential. We define the steady-state random variable $A = \lim_{t \rightarrow \infty} A(t)$, where the latter limit is defined in terms of weak convergence. Let $f_A(\cdot)$ be the equilibrium density of A . A level-crossings argument [11] leads to the balance equation

$$f_A(x) = \mu \int_x^\infty [1 - G(w - x)] f_A(w) dw. \quad (14)$$

To better understand the balance equation (14) note that the left-hand side (the steady-state density of $\mathbf{A}$) is interpreted as the long-run average number of up-crossings of level $x > 0$. Accordingly, the right-hand side represents the long-run average number of down-crossings of the same level. However, down-crossings of level x may occur only at moments of negative jumps. Indeed, μ is the rate of the negative jumps and $\int_x^\infty [1 - G(w - x)] f_A(w) dw$ is the probability that an arbitrary jump that starts from level $w > x$ is greater than $w - x$, which means that the latter jump is also a down-crossing of level x [11].

Rewriting Equation (14)

$$f_A(x) = \mu \int_0^\infty [1 - G(y)] f_A(y + x) dy \quad (15)$$

and differentiating, we get

$$f'_A(x) = \mu \int_0^\infty [1 - G(y)] f'_A(y + x) dy, \quad (16)$$

where $f'_A(x)$ is the derivative of $f_A(x)$ with respect to x . We know that, for $\rho > 1$, A has a unique density. Noticing that $f'_A(x)$ and $f_A(x)$ satisfy the same equation, it follows that $f'_A(x)$ equals $f_A(x)$, up to a multiplicative constant.

Solving $f'_A(x) = \eta f_A(x)$ with $\int_0^\infty f_A(x) dx = 1$ yields

$$f_A(x) = \eta e^{-\eta x}, \quad x > 0. \quad (17)$$

Here η is implicitly defined as the unique solution, in $(0, \mu)$, of

$$\eta = \mu[1 - G^*(\eta)]. \quad (18)$$

The fact that η satisfies Equation (18) follows from the substitution of Equation (17) in Equation (14). The uniqueness statement follows since $G^*(0) = 1$, $G^*(\infty) = 0$ and $G^*(\alpha)$ is a monotone decreasing convex function, which combined with $\rho > 1$ implies that the derivative of the right-hand side of Equation (18) is $1/\rho < 1$. We conclude that the steady-state law of the process $\mathbf{A}$, that is, the conditional AWT process of the $G/M/1$ queue in which the idle periods are deleted, is exponentially distributed(η).

The last argument implies that the *peak* points (i.e., points of local maximum) of the conditional $G/M/1$ queue are also exponentially distributed(η) (the latter statement is a well-known result [2]). To see this, note that the peak values of the AWT process are obtained at the arrival instants of the Poisson process $\mathbf{N}$. Hence, by PASTA [6], the limiting distribution of the peak values of the conditional AWT process equals the stationary distribution (17).

From the above, one can conclude that the sojourn times are also exponentially distributed(η). The validity of the latter statement follows from the fact that $\mathbf{A}$ is the conditional AWT process in which the idle periods are deleted. Now, consider a modified version of the AWT process $\mathbf{A}$. In this modification, the idle periods are added back at the end of the busy periods. Practically, we construct the modified version $\bar{\mathbf{A}} = \{\bar{A}(t) : t \geq 0\}$ of $\mathbf{A}$ such that at moments of negative overflows in $\mathbf{A}$, an interval whose size is equal to the negative overflow is added (during that interval the value of the modified process is 0). By this modification, the values of the peak points of $\bar{\mathbf{A}}$ and that of $\mathbf{A}$ are the same; thus, they also have the same steady-state laws. But, in the unconditional AWT process $\bar{\mathbf{A}}$, the peak points can be interpreted as the sojourn times in the $G/M/1$ queue.

Next, let $F_{\bar{A}}(x) = \lim_{t \rightarrow \infty} \Pr(\bar{A}(t) \leq x)$ be the steady-state distribution of $\bar{\mathbf{A}}$. Then,

$F_{\bar{A}}(0)$ is the probability that the $G/M/1$ system is empty. We have from Equation (17)

$$1 - e^{-\eta x} = \frac{F_{\bar{A}}(x) - F_{\bar{A}}(0)}{1 - F_{\bar{A}}(0)}, \quad (19)$$

because the right-hand side of Equation (19) represents the conditional distribution of $\bar{A}$ given $\bar{A} > 0$. To compute $F_{\bar{A}}(0)$ one can apply renewal theory to get

$$F_{\bar{A}}(0) = \frac{EI}{EI + ET},$$

where I designates the idle period and T designates the busy period (the law of I and T is analyzed in the section titled “Busy Period and Idle Period” below).

Finally, to obtain the law of the waiting time, recall that the sojourn time is the sum of the waiting time plus the service, where the latter two random variables are independent. In terms of LST this yields

$$\frac{\eta}{\eta + \alpha} = f_W^*(\alpha) \frac{\mu}{\mu + \alpha},$$

where $f_W^*(\alpha)$ is the LST of the waiting time. Thus,

$$f_W^*(\alpha) = \frac{\eta(\mu + \alpha)}{\mu(\eta + \alpha)}.$$

BUSY PERIOD AND IDLE PERIOD

For an arbitrary distribution G in the $G/M/1$ queue, the idle period I and the busy period T are not necessarily independent random variables. In the special case for which G is an arbitrary phase-type distribution, I and T are conditionally independent given the phase in which the busy period is terminated (I and T are independent random variables only when G is exponential, when the $G/M/1$ system becomes an $M/M/1$ system, and when I is also exponential).

For general G there are several methodologies for computing the joint law of I and T (different approaches can be found in text books [1–4]). We adopt an approach (based on a sequence of recent works [7,10,12–15] and use the notation as defined in the section titled “Work and Attained Waiting Time.”

In other words, the continuous-time random walk $\mathbf{X}$ is composed of a drift of rate 1 minus a compound Poisson process with rate μ and iid jumps having distribution G . Define the stopping time $T = \inf\{t : X(t) \leq 0\}$. Note that $X(T) < 0$. The random vector $(T, -X(T))$ can be interpreted as the busy period and the idle period, respectively, of the $G/M/1$ queue (note again that T and $X(T)$ are not necessarily independent, unless the jumps are exponential).

To compute the joint law of $(T, -X(T))$ in terms of LSTs, we introduce the functionals $k(x, \alpha_1, \alpha_2)$ and $K(s, \alpha_1, \alpha_2)$ defined by $Re(\alpha_1, \alpha_2) \geq 0, x \geq 0$

$$k(x, \alpha_1, \alpha_2) = E\left(e^{-\alpha_1 T - \alpha_2 I} \mid Z_1 = x\right), \quad (20)$$

and

$$K(s, \alpha_1, \alpha_2) = \int_0^\infty e^{-sx} k(x, \alpha_1, \alpha_2) dx. \quad (21)$$

Also, let $\hat{s} = \hat{s}(\alpha_1)$ be the unique zero of $1 - \frac{\mu}{\mu - s} G^*(\alpha_1 + s)$ in the right-half α_1 -plane [2, p. 226]; such that

$$1 - \frac{\mu}{\mu - \hat{s}} G^*(\alpha_1 + \hat{s}) = 0 \quad (22)$$

Then, by the law of total probability and conditioning successively on the events $\{S_1 \geq x\}$ and $\{S_1 < x\}$ we can write

$$\begin{aligned} k(x, \alpha_1, \alpha_2) &= \int_{t=x}^\infty e^{-\alpha_1 t} e^{-\alpha_2(t-x)} dG(t) \\ &\quad + \int_{z=0}^\infty \mu e^{-\mu z} \int_{t=0}^x e^{-\alpha_1 t} \\ &\quad \times k(x-t+z, \alpha_1, \alpha_2) dG(t) dz. \end{aligned} \quad (23)$$

Taking the Laplace transform with respect to x and changing the order of integration yields

$$\begin{aligned} K(s, \alpha_1, \alpha_2) &= \int_0^\infty e^{-(\alpha_1+s)x} \int_0^\infty e^{-\alpha_2 u} dG(x+u) dx \\ &= \int_0^\infty e^{-(\alpha_1+s)x} \int_0^\infty e^{-\alpha_2 u} dG(x+u) dx \end{aligned}$$

$$\begin{aligned} &+ \mu \int_0^\infty e^{-(\alpha_1+s)t} dG(t) \int_0^x e^{-su} \\ &\times \int_0^x e^{-\mu z} k(u+z, \alpha_1, \alpha_2) dz du \\ &= \frac{G^*(\alpha_1+s) - G^*(\alpha_2)}{\alpha_2 - \alpha_1 - s} + \mu G^*(\alpha_1+s) \\ &\times \frac{K(s, \alpha_1, \alpha_2) - K(\mu, \alpha_1, \alpha_2)}{\mu - s}, \end{aligned} \quad (24)$$

so that

$$\begin{aligned} K(s, \alpha_1, \alpha_2) &\left[1 - \frac{\mu}{\mu - s} G^*(\alpha_1 + s)\right] \\ &= \frac{G^*(\alpha_1 + s) - G^*(\alpha_2)}{\alpha_2 - \alpha_1 - s} \\ &\quad - \frac{\mu}{\mu - s} G^*(\alpha_1 + s) K(\mu, \alpha_1, \alpha_2). \end{aligned} \quad (25)$$

Substituting $s = \hat{s}$ in Equation (25), we get

$$K(\mu, \alpha_1, \alpha_2) = \frac{G^*(\alpha_1 + \hat{s}) - G^*(\alpha_2)}{\alpha_2 - \alpha_1 - \hat{s}} \quad (26)$$

and by definition $\mu K(\mu, \alpha_1, \alpha_2)$ is the joint LST of the busy period and idle period. Also, by using $\alpha_1 = \alpha_2 = \alpha$ in Equation (26) we get the LST of the busy cycle $C = I + T$. Note also that

$$\begin{aligned} K(s, \alpha_1, \alpha_2) &= \frac{\mu - s}{\mu - s - \mu G^*(\alpha_1 + s)} \left[\frac{G^*(\alpha_1 + s) - G^*(\alpha_2)}{\alpha_2 - \alpha_1 - s} \right. \\ &\quad \left. - \frac{\mu}{\mu - s} G^*(\alpha_1 + s) \frac{G^*(\alpha_1 + \hat{s}) - G^*(\alpha_2)}{\alpha_2 - \alpha_1 - \hat{s}} \right]. \end{aligned} \quad (27)$$

As a by-product of the functional introduced in Equation (27) one can also introduce the joint asymptotic law of the AWT and the time elapsed since the beginning of the busy period via a martingale approach. To see this, consider the process $\mathbf{M} = \{M(t) : t \geq 0\}$, where

$$\begin{aligned} M(t) &= [\varphi(\alpha_2) - \alpha_1] \int_0^t e^{-\alpha_1 s - \alpha_2 X(s)} ds \\ &\quad + 1 - e^{\alpha_1 t - \alpha_2 X(t)}, \end{aligned} \quad (28)$$

and $\varphi(\alpha_2) := \alpha_2 + \mu[1 - G^*(-\alpha_2)]$ is the exponent of $X(t)$. Then, $\mathbf{M}$ is a special case of the *Kella–Whitt* martingale [16,17]. By applying the optional sampling theorem with the stopping time T to the martingale $\mathbf{M}$ we see that $E(M(T)) = 0$, thus obtaining the fundamental identity (with the substitution $X(0) = 0$)

$$\begin{aligned} [\varphi(\alpha_2) - \alpha_1]E \int_0^T e^{-\alpha_1 s - \alpha_2 X(s)} ds \\ = -1 + Ee^{-\alpha_1 T - \alpha_2 X(T)} \\ = -1 + \mu K(\mu, \alpha_1, -\alpha_2), \end{aligned} \quad (29)$$

where the second equality in Equation (29) follows since by Equation (20)

$$E(e^{-\alpha_1 T + \alpha_2 I}) = \mu K(\mu, \alpha_1, -\alpha_2).$$

Now define the random variable L as the asymptotic age of the busy period in the $G/M/1$ queue. That is, L is the time elapsed since the beginning of the busy period in steady state; in other words, L is the asymptotic age of the busy period. Accordingly, by the theory of regenerative processes [17] it follows that

$$\frac{E \int_0^T e^{-\alpha_1 s - \alpha_2 X(s)} ds}{ET} = Ee^{-\alpha_1 L - \alpha_2 A}. \quad (30)$$

Also, by *level crossing theory* [11], level 0 is down-crossed by the AWT only once during a cycle—at the end of the busy period. Thus, by Equation (17)

$$ET = 1/f_A(0) = 1/\eta. \quad (31)$$

Substituting Equations (30) and (31) into Equation (29) we get

$$Ee^{-\alpha_1 L - \alpha_2 A} = \frac{\eta[-1 + \mu K(\mu, \alpha_1, -\alpha_2)]}{\alpha_2 + \mu[1 - G^*(-\alpha_2)] - \alpha_1}.$$

SUMMARY

The $G/G/1$ queueing system is the prototype general single server queueing model. However, for the general $G/G/1$ queue, most of the

relevant measures and functionals cannot be expressed in closed form formulas. Thus, the two dual special cases—the $M/G/1$ queue and the $G/M/1$ queue—represent the pillar models. In practice, the $M/G/1$ model is more natural than the $G/M/1$ model since the memoryless assumption of the service in the latter model is unnatural. However, one can interpret the structure of the AWT process as the content level of the cash fund of insurance risk models with a constant input of premium, and compound Poisson arrivals of claims with general claim sizes. Then, the time of ruin and the deficit in the insurance risk model are interpreted as the busy period and the idle period in the $G/M/1$ model. One could think of many ramifications of the basic $G/M/1$ model. For example, under the insurance risk interpretation it is natural to model the content level of cash funds in which the input of premiums is state dependent (a special case of the latter assumption is the finite capacity case, see Löpker and Perry [18] and Perry *et al.* [19] for some variants). Other examples are those of the models with vacations, models with Abandonments, and models with priority disciplines. In this study, only the main interest factors were reviewed, such as the number of customers in steady state and the waiting time, the sojourn time, the busy period, and the idle period. The analysis was based on the duality between the $M/G/1$ model and the $G/M/1$ model.

THE GLOBAL REPLENISHMENT PROBLEM

JAMES R. BRADLEY
HÉCTOR H. GUERRERO

William and Mary, Williamsburg,
Virginia

INTRODUCTION

In recent years, manufacturers and retailers have increasingly sourced their raw materials and their retail goods overseas. This has led to the extensive use of intermodal transport to deliver globally sourced goods through the supply chain and to the eventual consumer. The value of imports into the United States grew at approximately an 8.4% compounded annual growth rate from 1990 through 2008 [1]. Even Wal-Mart, the nation's largest retailer, which in the 1980s promoted goods "Made in America," has relied on imported goods, importing \$12 billion of goods from China in 2002 [2]. While the importance of global replenishment has grown, long transportation lead times and the demand uncertainty over replenishment lead times have made managing global replenishment perhaps more difficult than domestic replenishment. Fortunately, global supply chains can be structured so that they have the flexibility to adjust replenishment quantities and destinations while goods are in transit in reaction to the revelation of demand information during long replenishment cycles. Macy's, for example, relies on such flexibility with its shipments from Asia [3], which also requires appropriate information technology and decision support systems. This flexibility to postpone the final replenishment decision is of value not only in retail distribution but also to manufacturers who might reapportion replenishment quantities among multiple factories depending on demand and production during transit. This

article discusses the replenishment decisions in flexible supply chains where the original replenishment decision can be revisited, and we place the analysis of those decisions in context with existing research, and we also suggest future research directions.

The flexibility discussed above stems from the many ways that a shipment from overseas might be routed once it arrives in the United States as shown in Figure 1:

1. Direct transit from the port to a final destination, which might be a factory for a manufacturer or a regional distribution center (RDC) or retail store for a retailer
2. To an import distribution center (IDC), which is a facility where goods not immediately needed downstream are stored [4,5]
3. To a crossdocking facility where the contents of containers can be deconsolidated and mixed in outgoing containers or trailers for immediate transfer downstream.

Thus, by providing information systems that continually monitor demand and decision models that can provide a better updated distribution solution, the original shipment decision can be revisited during transit to either (i) change the destination of whole containers, or (ii) resort the contents of containers at a crossdocking facility. A container's destination might be changed, for example, from an IDC to a crossdocking facility if a surge in retail demand causes some or all of the goods to be needed immediately downstream in the supply chain. Resorting the contents of containers at a crossdocking facility allows a response to more recent demand and provides for more accurate replenishment. IDCs might be operated by a company doing its own distribution or by a third party logistics provider (3PL). Crossdocking facilities are often operated by 3PLs such as Maersk Distribution [6] or NYK Logistics [7].

Figure 1. Alternative global supply chain routes.

One might consider the problem of determining the optimal replenishment decisions in the short term as (stochastic) demand varies in an otherwise static business environment. However, the benefits resulting from this flexibility also extend to situations where business environment parameters change. For example, when diesel fuel prices surged above \$4 per gallon in 2008, logistics managers planned changes in their supply chains [8], including (i) transitioning from just-in-time delivery to full truckloads, (ii) a renewed emphasis on increased packing density, (iii) reduced stock keeping unit (SKU) counts, and (iv) transitioning from trucking to less costly shipping modes such as rail. While we might not expect that exact same shock to the business environment to reoccur, other changes in the parameters under which replenishment decisions are made undoubtedly will occur and flexibility in supply chain operations will be rewarded in those circumstances. For example, recent increases in container rental fees due to shipping lines' efforts to increase revenue have

greatly increased the cost of using containers [9]. The cost of using containers can also change significantly for particular origins and destinations as container owners realign container charges and shipping fees in order to rebalance container flow throughout the world. The amount of time that a shipper can maintain possession of a container before additional charges accrue also changes over time. Besides the costs of shipping, fuel, and containers, the costs of labor, exchange rates, and inventory vary over time, each of which might motivate a change in supply chain flows that would reduce cost. Flexibility makes it possible to shift operation modes quickly in reaction to the changing business environment, for example, by increasing the use of crossdocking facilities to transload goods from containers into semitrailers for logistics efficiency when container fees increases.

We proceed in the next section (titled "A General Description of Decisions in the Flexible Global Supply Chain") by generally describing the replenishment decisions in

a global supply chain. In the section titled “Formulation for Replenishment Decisions in Flexible Global Supply Chains,” we present a formulation for those replenishment decisions and relate it to the existing literature. We conclude in the section titled “Conclusions.”

A GENERAL DESCRIPTION OF DECISIONS IN THE FLEXIBLE GLOBAL SUPPLY CHAIN

For the remainder of this article, we discuss the problem in the context of a large retail distribution supply chain, which is likely to be a more general structure than that for a manufacturer. The manufacturer’s network generally has fewer echelons because no link is needed between the IDC/crossdock echelon of the supply chain and the factories (which take the place of retail stores in Fig. 1). This is because a large retailer, for example, Wal-Mart, might have thousands of stores, whereas even large manufacturers might only have tens of plants. Our discussion, therefore, is without loss of generalization because the manufacturer’s problem has a simpler supply chain and, otherwise, is likely to be of smaller dimensions (e.g., number of goods and number of destinations) as well. With Wal-Mart or Target in mind, our discussion about the global supply chain in Fig. 1 references a US port throughout the article, although our discussion is relevant for import supply chains into any country.

Global supply chains due to necessity use intermodal transportation where one link is ocean transport: the only other intercontinental transportation alternative, air freight, is too expensive for most goods. Moreover, the types of goods ordered by the manufacturers and retailers that we consider in this article would be shipped in containers. In other words, this article is not concerned with bulk shipments of commodities such as coal, iron ore, or wood products. Containerized freight movements are indeed significant and constituted 70% of global trade in 2000 [10]. The percentage of freight traveling via container continues to increase at an estimated 8.7% annual growth rate [11]. Although our focus

is on globally sourced supply, the basic decisions we discuss could also be faced by domestically based supply chains that are far-flung. Thus, our concern is centered on goods that move through some intermodal network—ocean carriers via containers to truck via trailers and possibly by rail.

The presence of an IDC and/or crossdock offers great flexibility in routing containers from the receiving port (ultimately) to the RDCs, which serve many retail locations (see Fig. 1). A highly assorted container, with many SKUs and relatively small quantities of each SKU, might be shipped directly to an RDC, thus bypassing the IDC and crossdock and avoiding the associated costs. These containers might require an overseas consolidation step if a particular manufacturer does not manufacture a sufficiently wide variety of goods. Small delivery quantities can alternatively be created at a US crossdocking facility using goods from containers with larger quantities of fewer SKUs. Some containers with fewer SKUs and greater quantities of each SKU might also go directly to the IDC if they are not immediately needed downstream, and the IDC might also receive goods from the crossdocking facility if in reconsolidating a container some goods are not needed immediately downstream at an RDC. These options create flexibility because the destinations of the goods in ocean-bound containers with fewer SKUs and larger lot quantities can be postponed until a short time before landfall [3], at which time they can be directed toward the location, either a crossdocking facility or an IDC, where they would offer the greatest advantage. Taking best advantage of this flexibility requires that an appropriate assortment of two types of loads be created overseas, with some loads that are highly assorted and destined for RDCs and some containers with larger batch sizes destined for the IDC or a crossdocking facility. Creating that assortment can be broken down into three decision components as follows:

1. How many containers to ship.
2. Which SKUs and how many of each SKU to load in each container.
3. The intended destination of each container.

Making the best decision requires that the economics of each route be considered along with the uncertainty of demand. Creating an assorted load overseas avoids charges that accrue at the US IDC and crossdocking facility. Additionally, the lesser quantities of the many SKUs in an assorted container would quickly flow through an RDC, thus minimizing inventory cost, as well as helping to avoid having the problem of shipping great quantities to one RDC, which are later found to be required at another RDC. However, these savings are in some cases offset to some degree by a cost to consolidate the load overseas before shipping. We might expect that overseas consolidation would be less costly, however, than consolidation in an US crossdocking facility: labor in many countries is less than in the United States. A more subtle cost might be imposed on creating a more highly assorted load overseas if the mix of SKUs and their quantities on that load destined for an RDC no longer proved to be a wise choice once the container arrives in the United States. The difficulty of an overseas determination of the appropriate mixes of assorted shipments for RDCs due to uncertain demand and long transit times motivates a mix of (i) more highly assorted containers and (ii) other loads with greater quantities of fewer SKUs that could be used to customize loads for RDCs with a reduced lead time from the point of customization. This is called *postponed replenishment*. Of course, greater cost is incurred for handling the loads with a lesser assortments at the crossdocking facility because these goods stay in the pipeline longer (particularly those stored at the IDC), thus accruing labor and inventory holding cost.

Given that the original replenishment decision can be revisited at some point during the ocean voyage, one would ideally postpone the final decision regarding the routing and handling of the containers until they arrive at the port. Some lead time is required, however, to arrange for the transportation of the containers and for planning staffing requirements at crossdocking facilities, which is called the *logistics planning and acquisition lead time* (L_2). The total transportation lead time is $L = L_1 + L_2$, where, given L and

L_2 , L_1 is how long the final replenishment decision can be delayed, which is called the *decision postponement lead time*. See Table 1 for a breakdown of events that occur within these two lead time components. Note that the lead time to the IDC, RDCs, and retail stores on the landside of the supply chain is in addition to L and it varies depending on which facilities the goods pass through en route to the destination. The lead time L is determined by the schedule for a *trade lane* for a shipping line. Shipping lines offer scheduled service at posted origins and destinations. For example, Maersk Line offers a trade lane that takes two weeks to travel from Rotterdam to Norfolk, VA and stops in Bremerhaven, Felixstowe, and Newark before arriving in Norfolk. Multiple ships follow this sequence of ports so that a ship arrives in Norfolk every seven days. Thus, in this example, $L = 14$ days and two container ships are in the pipeline at any one point in time.

Replenishment decisions for goods sourced overseas can be either in the context of a one-time purchase or the continuous replenishment of goods stocked on retail store shelves. One-time purchases that retailers do not intend to continuously stock are made, for example, in the case of “dollar stores” for over-run or close-out goods [12], and also by traditional retailers such as Target and Walmart for seasonal goods (e.g., lawn furniture in spring and holiday decorations in Winter). Retailers, large and small, also carry items on a continuous basis for a long period: these items require ongoing replenishment orders to keep the retail shelves stocked. Manufacturers also require continuous supply of offshored raw materials for products that are produced on a sustained basis. Intermediate modes of procurement between these two end points on the continuum are also possible where, for example, a small number of replenishment orders might be placed within a selling season such as in the case with Sport Obermeyer [13]. Another such intermediate example is the case of a product for which initial demand will spike, such as a Harry Potter novel. The large initial purchase might be followed up with many replenishment orders over a finite time horizon. The formulation

Table 1. Global Transport Lead Time Components

Lead Time Components	Events
Decision postponement lead time L_1	Loading of goods into the container
	Transporting container to port terminal (truck/rail)
	Handling/waiting at origin port and loading container onto ship
	Initial portion of ocean voyage
Logistics planning and acquisition lead time L_2	Remainder of ocean voyage after recourse decision
	Unloading container from vessel
	Handling/waiting at port for pickup

that we present in the next section can be used in both contexts.

The maximum size of this problem might be fairly estimated by the parameters of Wal-Mart's supply chain and, in particular, the portion of their supply chain used for nonperishable goods. Wal-Mart supercenters stock on the order of 100,000 SKUs (<http://www.retailingworks.com/why.htm>), perhaps 30–50% of which are nonperishable and flow through their IDC–RDC supply chain echelons to retail stores. Wal-Mart manages much of its own logistics including 147 distribution centers, 7,200 tractors, and 53,000 semi-trailers (<http://walmartstores.com/download/2336.pdf>). Each RDC serves between 75 and 100 retail stores within a 250-mile radius. It is reported that \$12 billion of Wal-Mart's goods in 2002 were sourced in China, and so its imports as measured in containers are considerable given that its China-based import department sources in 18 other countries as well (<http://walmartstores.com/download/3719.pdf>).

FORMULATION FOR REPLENISHMENT DECISIONS IN FLEXIBLE GLOBAL SUPPLY CHAINS

We now present the economic parameters for global replenishment decisions, followed by a formulation for the problem. We then consider various simplifying assumptions correlating the resulting problems to the existing literature, and we also comment on the advantages and disadvantages of the

simplified problems in terms of providing managerial insight.

The Economics of Global Shipping

In this section, we describe the relevant costs for replenishment decisions in a global supply chain, as summarized in Table 2. Costs accrue due to many different bases, including per container, per unit of time, per order line item, per shipment value, and so on, at the different supply chain links. The data in Table 2 is based on the assumption that the “shipper” owns the IDC and RDC links of the distribution supply chain such as would be the case with national retail chains (e.g., Wal-Mart and Target). We also assume, as is often the case, that the crossdocking facility is operated by a 3PL provider such as Maersk Distribution or NYK Logistics. The formulation that we present in the following section takes into account the relevant costs from Table 2 that would affect both the overseas and postponed replenishment decisions.

Formulation for the Global Replenishment Problem

In this section, we construct a formulation for replenishment of the RDCs for goods that are received from one port of call on one shipping lane, which is a kernel of a potentially larger problem. We discuss the effect of expanding the scope of the problem, and also discuss relaxing the simplifying assumptions that we make below. We also address extensions of this problem that consider various important features of real-world supply chains.

Table 2. Summary of Global Supply Chain Costs and Bases of Charges

<i>Supply Chain Links</i>	
Facility/Link Type	Relevant Charges
Port marine terminal	• Per instance charges – Per container lift – Per move • Per day charges – Demurrage for storage past free-time allowance
Consolidator (third party)	• Per container charge
Crossdock/transload (third party operation)	• Per container charge for transloading
International DC	• Per value of inventory, per time – Holding cost • Fixed cost – Building and assets – Some portion of labor • Variable handling cost – Some portion of labor
Regional DC	• Per value of inventory, per time – Holding cost • Fixed cost – Building and assets – Some portion of labor • Variable, per-container/trailer handling cost – Some portion of labor
<i>Transportation Links</i>	
Ocean liner	• Per container – Transport fee • Per day charges – Container demurrage past free-time
Trucking (dray move, container)	• Per container, per trip charge
Trucking (long haul, semitrailer)	• Per load, per trip charge based on distance, weight, and other factors
Trucking (LTL)	• By weight and distance
Railroad	• By weight and distance
Barge	• Per load, per trip
<i>Logistics/Supply Chain Facilitators</i>	
Freight forwarder	• Per transaction charges • Per container charges • Per item charges – Customs tariff code classification
Insurance	• Per product value in container

Table 3. Decision Epochs

Decision	Decision Epochs
Original replenishment decision	$t = 0$
Postponed replenishment decision	$t = L_1$
Allocation of IDC inventory to RDCs	$t = 1, \dots, T$

Our simplifying assumptions begin with the assumption that the transportation lead time $L = T$ days, and thus a ship arrives every T days such that containers on only one ship are in transit at any time. Within the T -day horizon, three different types of decisions are made as shown in Table 3 where we have indexed time (days) using t . These decision epochs would be repeated for goods that are continuously replenished, whereas a single problem with a horizon of T days suffices for a one-time buy. We assume that ships arrive according to schedule (deterministic arrivals) and that lead times from ports to the IDC and RDCs, and lead times from the IDC to RDCs, are deterministic. Also, without loss of generality given the foregoing assumptions, we assume zero lead time from the IDC to each RDC, and from the port to the IDC and all RDCs. Including nonzero lead time in the formulation is straightforward.

A set of sequential problems that addresses the relevant decisions for each period are summarized in Table 4; formulations for these problems are shown below

using the notation in Table 5. Using a backward solution procedure, Θ_1 would be solved, followed by Θ_2 , and finally Θ_3 . The problems are shown as parameters that (i) indicate the current inventory state of the system, and (ii) solutions from prior problems that bear on the solution of the current problem.

In the initial formulation, we consider the stochastic demand, where $D_{p,r,t}$ is a random variable of demand for product p at RDC r in period (day) t . (See Table 5 for notation.) Later, we consider the problem simplified by assuming the deterministic demand. Our formulation considers only one IDC, although it is simple to formulate a problem with multiple IDCs. We represent shipping containers and truck trailers as having only a volume constraint, which we represent as a volume V for containers and V' for loads leaving the crossdocking facility. The specification of two volumes offers the opportunity to use trailers on loads leaving the crossdocks for RDCs. The formulation is easily extended if multiple types of loads with multiple volumes are used at the crossdock. Extending this formulation to accommodate a weight restriction is easy, although this impacts the computational requirements, which we comment on later. We also ignore determining detailed packing plans for containers, which would greatly complicate the solution.

Our formulation accommodates the varying logistics costs of different routes that goods might take. First, the formulation

Table 4. Sequential Problems

Problem	Periods	Decisions Considered
Θ_1	$t = L_1 + 1, \dots, T$	Daily shipments from IDC to RDCs
Θ_2	$t = L_1$	- Daily shipment from IDC to RDCs - Postponed replenishment decision
Θ_3	$t = 0, \dots, L_1 - 1$	- Daily shipments from IDC to RDCs in period $t = 1$ on - Original replenishment decision in period $t = 0$

Table 5. Notation*Economic Parameters*

h_p	Holding cost rate for product p at the IDC
h'_p	Holding cost rate for product p at and RDC
b'_p	Backorder cost of product p in period t
c_r	Cost of shipping a load from the IDC to RDC r
c_I	Cost of logistics route where a container is shipped from the port to the IDC
c_C	Cost of shipping a container to the crossdock and deconsolidation (handling/labor)
c'_r	Cost of shipping a container directly to RDC r
c_{CI}	Cost of shipping route where a load is shipped from the crossdock to the IDC
c_r^{PR}	Cost of shipping a load from the crossdock to RDC r

Demand

$D_{p,r,t}$	Random variable of demand for product p at RDC r in period t
-------------	--

Inventory Variables

$I_{p,t}$	Inventory of product p in period t at the IDC
$I_{p,r,t}^+$	(Positive) on-hand inventory of product p in period t at RDC r
$B_{p,r,t}$	Backorders of product p in period t at RDC r

Decision Variables

S_r^{IR}	Cost of shipping a load from the IDC to RDC r
$s_{r,u,t}$	1 if load u is used from the IDC to RDC r in period t
S^I	The number of loads shipped directly from the port to the IDC
s_w^I	1 if load w is shipped directly from the port to the IDC, and 0 otherwise
S_r^R	The number of containers shipped directly to RDC r in period L_1
$s_{r,w}^R$	1 if container w is shipped directly to RDC r , and 0 otherwise
S^C	The number of containers crossdocked in period L_1
s_w^C	1 if container w is crossdocked, and 0 otherwise
S_r^{PR}	The number of loads shipped from the crossdock to the RDC r in period L_1
S^{CI}	The number of loads shipped from the crossdock to the IDC in period L_1
$s_{r,y}$	1 if (outgoing) crossdocked load y is shipped to RDC r , and 0 otherwise
s_y	1 if (outgoing) crossdocked load y is shipped to the IDC
$x_{p,r,t,u}$	1 if product p is put on load u from the IDC to RDC r in period t
$x_{p,r,y}$	1 if product p is put on (outgoing) crossdocked y for RDC r
$x_{p,y}$	1 if product p is put on (outgoing) crossdocked y for the IDC
$q_{p,r,t}$	Quantity of product p shipped from RDC r in period t
Q'_p	Quantity of product p crossdocked to IDC in period L_1
$Q'_{p,r}$	Quantity of product p crossdocked to RDC r in period L_1

Other Parameters

v_p	Volume of each unit of product p
P	The number of products (SKUs) shipped from overseas
R	The number of RDCs
U	The available number of trucks/loads from the IDC to the RDCs
Y	The available number of trailers/loads from the crossdock to the IDC and the RDCs
W	Maximum number of containers to ship from overseas
V	Volume of a shipping container
V'	Volume of a container or a trailer for outgoing loads form the crossdocking facility
M	Sufficiently large value that exceeds the maximum units in any container or load

allows, if required, different holding costs at the IDC and RDC, which are h_p and h'_p respectively. The period backorder cost at the RDCs is b'_p per unit. Different logistics costs accrue depending on whether a container proceeds directly from the port to a particular RDC r (c'_r), or to the IDC (c_I), or to the crossdocking facility (c_C). The container cost c_C includes transportation and handling associated with deconsolidating at the crossdock. The outgoing costs at the crossdock are c_r^{PR} for consolidating a load for RDC r and shipping it, whereas c_{CI} is the cost of creating a load for the IDC and shipping it. The cost to create a load at the IDC and ship it to a particular RDC r is c_r . The handling cost of putting goods away at the IDC and then retrieving them for later shipping is consolidated in the aforementioned parameters c_I and c_{CI} : two such parameters allow accounting for differing effort levels that may be required. For example, a 40' container (from the port) would take less labor to unload than would a 53' trailer (from the crossdock). Any applicable overseas consolidation fee, as we discussed earlier, could be included in the parameters c'_r for each RDC r .

The lower case binary decision variables s_i are 1 if a particular container or trailer is used to transport a load on a particular origin–destination pair, and zero otherwise. The S_i upper case integer parameters accumulate the number of loads employed between a particular origin–destination pair. The formulation can be rewritten to avoid these latter parameters, but we include them for greater clarity.

Lastly, the decision variable $q_{p,r,t}$ is the shipping quantity of product p from the IDC

to RDC r in period t . The upper case $Q_{p,w}$ indicates quantities of each product p in container w , whereas Q'_p and $Q'_{p,r}$ indicate shipping quantities of product p to the IDC and RDC r , respectively, for goods after they have been crossdocked.

Problem Θ_1 determines the optimal shipping quantities of each product p from the IDC to each RDC r in time periods $t = L_1 + 1, \dots, T$ ($q_{p,r,t}$) in order to minimize the holding cost at both the IDC and RDCs, as well as backorder costs at the RDC. (Backorder costs are charged only at the RDC, which is the closest echelon to the final customers where inventory shortages have an immediate monetary effect in terms of lost sales.) Constraints (1) and (2) are inventory balance equations for the IDC in consideration of the quantity Q'_p of product p that arrives at the IDC in period T . Constraints (3) and (4) are inventory balance equations for each RDC r in consideration of the shipment $Q'_{p,r}$ that each RDC r receives in period T . Constraint (5) accounts for (positive) on-hand inventory, while constraint (6) accounts for backorders at the RDCs. Constraint (7) requires that the total shipping quantity of a product should not be greater than its on-hand inventory. Constraints (8) through (13) are a multiple knapsack problem that allocate goods among the U available trucks. Constraint (11) requires that the entire quantity of each product p shipped to RDC r be placed on the same load u , thus simplifying the form of constraint (8), which keeps the contents of each truck within the volume capacity V' .

$$\Theta_1(\{Q'_p\}_{p \in P}, \{Q'_{p,r}\}_{p \in P, r \in R}, \{I_{p,L_1}\}_{p \in P}, \{I_{p,r,L_1}\}_{p \in P, r \in R})$$

$$= \min \mathbf{E} \left\{ \sum_{t=L_1+1}^T \left\{ \sum_{p \in P} \left[h_p I_{p,t} + \sum_{r \in R} (h'_p I_{p,r,t}^+ + b'_p B_{p,r,t}) \right] + \sum_{r \in R} c_r S_r^{IR} \right\} \right\}$$

s.t.

$$Q'_p \in \{0, 1, 2, \dots\} \quad p \in P \quad (14)$$

$$Q'_{p,r} \in \{0, 1, 2, \dots\} \quad p \in P; r \in R. \quad (15)$$

Problem Θ_2 determines the final replenishment decisions and, hence, the objective function accounts for logistics costs. The objective function also includes the cost of the subsequent Problem Θ_1 and the holding and backorder costs in period L_1 , analogous with Problem Θ_1 .

The binary decision variables s_w^I , s_w^C , and $s_{r,w}^R$, when set to 1, indicate that a particular container w will be sent directly to the IDC, crossdocked, or sent directly to RDC r , respectively. Constraint (3) ensures that each container is routed only once. Constraints

4–6 accumulate the number of containers that are sent to the IDC, crossdocked, and to each RDC r , respectively, in the variables S^I , S^C , and S_r^R , which are used in the objective function to account for the various logistics costs. Constraints (7) through (18) constitute a multiple knapsack problem, similar to that in Problem Θ_1 , except now the quantities of each product p that are crossdocked and reloaded into another container or trailer are limited by the quantity of incoming goods designated for crossdocking, as reflected in constraint (7).

$$\begin{aligned} & \Theta_2 \left(W, \{Q_{p,w}\}_{p \in P, w \in W}, \{I_{p,L_1-1}\}_{p \in P}, \{I_{p,r,L_1-1}\}_{p \in P, r \in R} \right) \\ &= \min E \left\{ \Theta_1(\{Q'_p\}_{p \in P}, \{Q'_{p,r}\}_{p \in P, r \in R}) + \sum_{p \in P} \left[h_p I_{p,L_1} + \sum_{r \in R} (h'_p I_{p,r,L_1}^+ + b'_p B_{p,r,L_1}) \right] \right. \\ & \quad \left. + \sum_{r \in R} c_r S_{r,L_1}^{IR} + c_I S^I + \sum_{r \in R} c'_r S_r^R + c_C S^C + \sum_{r \in R} c_r^{PR} S_r^{PR} + c_{CI} S^{CI} \right\} \end{aligned}$$

$$\sum_{r \in R} q_{p,r,L_1} \leq I_{p,L_1-1} \quad p \in P \quad (23)$$

$$\sum_{p \in P} v_p q_{p,r,L_1} x_{p,r,L_1,u} \leq V' \quad r \in R; u = 1, \dots, U \quad (24)$$

$$s_{r,u,L_1} \geq \frac{1}{M} \sum_{p \in P} q_{p,r,L_1} x_{p,r,L_1,u} \quad r \in R; u = 1, \dots, U \quad (25)$$

$$S_{r,L_1}^{IR} = \sum_{u=1}^U s_{r,u,L_1} \quad r \in R \quad (26)$$

$$\sum_{u=1}^U x_{p,r,L_1,u} = 1 \quad p \in P; r \in R \quad (27)$$

$$x_{p,r,L_1,u} \in \{0, 1\} \quad p \in P; r \in R, u = 1, \dots, U \quad (28)$$

$$s_{r,u,L_1} \in \{0, 1\} \quad r \in R; u = 1, \dots, U \quad (29)$$

$$Q_{p,w}, Q'_p, Q'_{p,r} \in \{0, 1, 2, \dots\} \quad (30)$$

The objective function of Problem Θ_3 accounts for the daily logistics costs of transferring goods from the IDC to the RDCs in periods 1 though $L_1 - 1$, just as in Problem Θ_1 . A decision is made in Problem Θ_3 regarding how many containers to ship initially and the quantity of each product in each container, which is represented by the decision variables $Q_{p,w}$. Constraint (12) limits the goods packed into each container w to the volume available. Although the initial shipping decision is made in this problem, no costs for shipping containers are accrued in the objective function of this problem. Instead, all logistics costs are accounted for

in Problem Θ_2 when replenishment decisions are finalized. The cost impact of the decisions $Q_{p,w}, r \in R, p \in P$, in problem Θ_3 comes later and depends on how much the original replenishment decision must be adjusted, as reflected in Problem Θ_2 .

Problem Θ_3 includes all of the constraints pertaining to the daily transfer of goods from the IDC to the RDCs for periods 1 though $L_1 - 1$, just as in Problem Θ_1 , with the exception that no goods are received over the time frame encompassed by Problem Θ_3 so that two constraints (2 and 4) in Problem Θ_1 are not required.

$$\begin{aligned} & \Theta_3 (\{I_{p,0}\}_{p \in P}, \{I_{p,r,0}\}_{p \in P, r \in R}) \\ &= \min \mathbf{E} \left\{ \Theta_2(W, \{Q_{p,w}\}_{p \in P, w \in W}, \{I_{p,L_1-1}\}_{p \in P}, \{I_{p,r,L_1-1}\}_{p \in P, r \in R}) \right. \\ & \quad \left. + \sum_{t=L_1-1}^T \left\{ \sum_{p \in P} \left[h_p I_{p,t} + \sum_{r \in R} (h'_p I_{p,r,t}^+ + b'_p B_{p,r,t}) \right] + \sum_{r \in R} c_r S_{r,t} \right\} \right\} \\ & \text{s.t.} \\ & I_{p,t} = I_{p,t-1} - \sum_{r \in R} q_{p,r,t} \quad p \in P; t = 1, \dots, L_1 - 1 \quad (1) \\ & I_{p,r,t} = I_{p,r,t-1} - D_{p,r,t} \quad p \in P; r \in R, t = 1, \dots, L_1 - 1 \quad (2) \\ & I_{p,r,t}^+ \geq I_{p,r,t} \quad p \in P; r \in R; t = 1, \dots, L_1 - 1 \quad (3) \\ & B_{p,r,t} \geq -I_{p,r,t} \quad p \in P; r \in R; t = 1, \dots, L_1 - 1 \quad (4) \\ & \sum_{r \in R} q_{p,r,t} \leq I_{p,t-1} \quad p \in P; t = 1, \dots, L_1 - 1 \quad (5) \\ & \sum_{p \in P} v_p q_{p,r,t} x_{p,r,t,u} \leq V' \quad r \in R; t = 1, \dots, L_1 - 1; u = 1, \dots, U \quad (6) \\ & s_{r,u,t} \geq \frac{1}{M} \sum_{p \in P} q_{p,r,t} x_{p,r,t,u} \quad r \in R; u = 1, \dots, U; t = 1, \dots, L_1 - 1 \quad (7) \\ & S_{r,t} = \sum_{u=1}^U s_{r,u,t} \quad r \in R; t = 1, \dots, L_1 - 1 \quad (8) \end{aligned}$$

The Global Replenishment Problem and Related Literature

In this section, we discuss the solution of the problem as outlined in the previous section and relate it to relevant literature. We first consider the solution of Θ_1, Θ_2 , and Θ_3 with a simplifying assumption that demand is deterministic. Subsequently, we consider possible solution methodologies with stochastic demand.

Before proceeding, we situate the framework of Problems Θ_1, Θ_2 , and Θ_3 in the contexts of ongoing replenishment and one-time purchases. The framework of Θ_1, Θ_2 , and Θ_3 was initially presented in the context of ongoing replenishment: Θ_1, Θ_2 , and Θ_3 constitute the problem for one replenishment cycle, and ongoing replenishment would be represented by a sequence of, perhaps, an infinite number of these replenishment cycles where the ending inventory of each cycle was the starting inventory of the next cycle. To represent a one-time purchase, one might consider only one ordering cycle, that is, solving Problem Θ_1, Θ_2 , and Θ_3 without repeating further cycles. In that case, we might extend the time horizon of Problem Θ_1 for some number of periods past time T , which is when selling would commence assuming that no prior inventory was in the IDC and RDCs. We would also want to include revenue in the objective function to penalize lost sales and, possibly, a salvage value at the end of the selling horizon. (In the continuous replenishment formulation, unfulfilled demand in any period is penalized by a backorder cost, which motivates some minimum service level.) This formulation structure allows investigation of the effectiveness of holding a portion of

the one-time purchase quantity back at the IDC until demand at the various RDCs is observed. Holding inventory back at the IDC in this fashion is not uncommon for seasonal products such as holiday decorations, and this practice is reminiscent of the accurate replenishment approach for replenishment of seasonal items where orders are placed two times within a selling season, and where the forecast of demand for the second order is based on sales of the goods in the first order [13]. A problem with a horizon intermediate between these two extremes might also be considered with a finite number of replenishment cycles. For example, considering two ordering cycles and enhancing the formulation by updating the demand forecast in the second cycle based on demand in the first cycle would create a generalized version of the accurate replenishment formulation.

The global replenishment problem, as we have described it, has only one stochastic element in the formulation, which is represented by $D_{p,r,t}$ for demand of product p at RDC r in period t . If we now assume that demand is deterministic, we are left with a purely deterministic, and simpler, problem. We begin by discussing that deterministic formulation. In this case, no uncertainty exists over the problem horizon so that we can determine the solution to all three problems simultaneously at the outset at time $t = 0$. Note that, although no realignment of goods at the US crossdock from container to container is needed due to demand uncertainty (the correct quantities of goods in containers can be loaded initially), realignment from container to truck trailer may be necessary for logistics efficiency (the contents of three 40' containers can normally be loaded into two 53' trailers). A single problem can thus be

written by combining all the constraints and objective function terms from all problems.

Such a problem involves (i) determining shipping quantities of each product, (ii) determining how many containers to ship and how many of each product to place in the containers, and (iii) how to deconsolidate and repack these goods that are crossdocked. The final two steps constitute two sequential multiple knapsack problems, the latter one (Problem Θ_2) being constrained by the former (Problem Θ_3) and the decision of which containers to repack. The literature on the multiple knapsack problem and other variants of the knapsack problem is extensive; two excellent references on exact and approximate solutions are Refs 14, 15. Note that the multiple knapsack problem is strongly NP-Complete [16]. Thus, two sequential multiple knapsack problems, where the first presents a constraint on the second, are even more complex than a single problem. Polynomial time approximation algorithms are available for a single multiple knapsack problem [16], which might possibly be employed for two sequential problems.

Although simplifying the problem by assuming deterministic demand would allow us some insight into how containers might be efficiently repacked on the US side of the supply chain for transportation efficiencies, it does not allow investigation of safety stock or what percentage of containers should be highly assorted for direct shipment to RDCs versus packed overseas with fewer SKUs for deconsolidation and resorting at a US crossdocking facility in reaction to demand revelation during transit. It is probable that uncertainty influences decision policies significantly and, although the global replenishment problem is still difficult with deterministic demand, this simplification will not provide some answers a manager might be seeking.

Simplifying the problem further, one might consider allowing shipping quantities to be continuous variables, which results in a binary integer program that is likely to be much simpler computationally. The binary variables that remain, s , determine how many containers or trailers are employed in each link of the supply chain. It might be

possible to prove convexity results in these variables (e.g., cost convexity in the number of containers shipped from overseas), which would make the computations easier, or perhaps an efficient branch and bound algorithm might be possible. (see the article titled **Branch-and-Bound Algorithms** in this encyclopedia.)

Solving Problems Θ_1, Θ_2 , and Θ_3 with stochastic demand adds complexity, which not only involves binary and integer decision variables but also stochastic demand in a multiple-stage multiple knapsack problem. Moreover, this sequence of problems must be solved repeatedly for continuous replenishment. Possible solution methodologies include dynamic programming, heuristic policies, and simulation.

Dynamic programming can be used to analyze this problem either analytically or numerically. A typical approach to proving structural results (e.g., convexity of an objective function) can be accomplished by applying calculus and the theory of dynamic programming (see the section titled "Dynamic Programming" in this encyclopedia). Such approaches can be used to prove the existence of a unique optimal solution, although they often fail at providing a closed-form solution. One complication of the formulation that we have presented is that each replenishment cycle requires the solution of three sequential problems. Furthermore, that sequence is repeated for continuous replenishment. A hierarchical approach to such problems has been developed whereby, in our context, the optimal solution for a single sequence of Problems Θ_1, Θ_2 , and Θ_3 is proven and, subsequently, dynamic programming theory is applied to a sequence of those embedded problems. Research that has considered embedding multiple decisions or "subperiods" within one period of a dynamic program includes Ref. 17.

When dynamic programming fails to provide for easy computation of the optimal solution, numerical methods can be used to compute an answer within an interval of the optimal solution. Two approaches are possible including value iteration and policy iteration (see **Approximate Dynamic Programming—II: Algorithms** and

Dynamic Programming, Control, and Computation.)

Discrete-event simulation models can also be used to address the global replenishment problem. Used in a “what-if” mode of investigation, this approach might help provide insight into effective decision policies, although it can neither prove the existence of an optimal solution nor can any solution be guaranteed to be optimal (see ***Introduction to Discrete-Event Simulation***). Simulation-based gradient search methods might also be applied to find optimal solutions numerically, provided the existence of the optimal solution and its structure have otherwise been proved (e.g., via dynamic programming). Infinitesimal perturbation analysis (IPA) is one such method that can be used to estimate the gradients of expected values of objective functions, although it can be applied only under certain conditions [18]. One of the conditions required by IPA is the continuity of the parameters with respect to which gradients are computed. For the decision variables that we would want to search over, our formulation contains binary variables representing decisions to load a particular container or truck and integer variables representing shipping quantities. Relaxing the problem to consider continuous shipping quantities might, perhaps, be an effective tack. However, relaxing the integrality of binary variables is very likely not a promising approach. Thus, IPA might be used to solve a portion of our overall formulation, while some algorithm to handle the binary variables would still be required.

If the complexity of the problem does not permit effective analysis by any of the foregoing methodologies, then other heuristic approaches might be applied. Specifically, one might apply policies that are known in the literature to be optimal in other circumstances, even though it is neither known nor likely that they are optimal for the global replenishment problem. For example, base-stock or (s, S) policies might be applied (using simulation to evaluate their effectiveness) and compared to determine which performs best. Other intuitive heuristics might also be applied, such as the following service level-based policy:

- specify a service level for replenishing each RDC from the IDC;
- specify a service to provide each RDC from the crossdocking facility;
- specify a service level for each RDC up to which assorted containers would be loaded overseas;
- specify a service level for aggregate RDC demand up to which nonassorted containers would be loaded overseas;
- develop an algorithm for adapting the replenishment quantities suggested by the service levels above to the loading constraints (e.g., container volume limitations).

This service level approach is analogous with the Newsvendor solution, although this problem has many more dimensions, greater complexity, and constraints not present in the basic Newsvendor model (see ***Newsvendor Models***). Thus, the extensive research on the constrained newsvendor problem or Newsvendor models with multiple periods might be applied to a portion of our formulation [19]. Of course, policies from practice might also be evaluated against competing alternatives. One such policy we have observed is replenishing RDCs based on point of sale data and, in a continuous-time mode, sending a truck directly to an RDC whenever it is filled.

Extensions

Many extensions to our formulation that reflect various facets of real-world supply chains are possible, some of which we outline in this section.

First, our formulation is for a single shipping lane where an origin port and a destination port are specified. The flows of goods are from manufacturers or sources of supply in the vicinity of the origin port. While the scope of the formulation encompasses many decisions, a higher-level formulation could be constructed with a broader scope to evaluate the value of integrating goods flow from many shipping lanes or from multiple ports on the same shipping lane, where goods from multiple origins could be crossdocked

together in the United States. That formulation could be constructed by integrating multiple replicates of our formulation.

The current formulation implicitly assumes that there are destinations for all containers before the containers arrive at the ports. This is not always the case in practice, and goods are sometimes stored in a container until a final decision regarding destination is made, in which case the containers might remain at the port and possibly incur storage charges. This extension could be incorporated by adding an additional stocking location to the formulation, which would represent storage at the port.

Our formulation assumes a zero lead time from the port to the IDC and RDCs, and from the IDC to the RDCs. We also did not incorporate a lead time to unload the goods at either the IDC or the RDC, which could be viewed as part of the lead time that we did represent. One could add a separate deterministic nonzero lead time for unloading at the IDC and RDCs, which would not greatly complicate the formulation. Further, we may want to represent the stochastic nature of transportation or unloading by representing each corresponding lead time as a stochastic random variable. Unloading lead time might vary due to fluctuations in container contents (small vs large items), daily fluctuations in staffing (e.g., absenteeism), fluctuations in the number of containers that arrive each day, or simply variations in daily efficiency. The last factor might motivate us to represent unloading lead time as an independent random variable, whereas the other circumstances might require other types of formulation enhancements. For example, fluctuations in container volume might be handled by adding constraints that limit how many containers can be unloaded on a given day. These enhancements could complicate the formulation quite significantly.

Two other possible extensions include the following:

- We have not considered downstream logistics that would incorporate truck routings that serve multiple RDCs or retail locations. A rich literature exists

on this topic of the Direct Shipping Problem [20–22]. This problem combines the problems of inventory control and vehicle routing to consider *inventory routing* models, thus combining inventory and transportation costs. In most formulations, a single depot (IDC, RDC, or crossdocking operation) services multiple retailers with a single product. We could extend the formulation developed here to incorporate this final stage of the supply chain. Of course, the solution of the extended formulation would be further complicated.

- We have offered a formulation for continuous replenishment and described how it can be adapted to one-time purchases. These approaches could be combined in a formulation that includes both one-time purchases and continuously replenished goods.

CONCLUSIONS

The global replenishment problem that we have described in this article is of growing importance in a world with increasing global trade. In relating the existing literature to the formulation that we present, we have noted where current research can address portions of the formulation or simplifications of the formulation, but no research has been carried out on the problem in total. Future research can then pursue several directions. First, efforts can be made to integrate many models, each of which addresses a portion of the problem. An approach such as that in Ref. 17 is one framework that might provide such integration, specifically among Problems Θ_1 , Θ_2 , and Θ_3 . However, additional work is needed to handle the complexity of these subproblems before they can be successfully integrated. A second direction would be to investigate simplifications of the formulation that we have provided. As is always the case, the challenge with this tack is to find a simplification that is both tractable and a meaningful representation of the problem. Finally, heuristic approaches are always possible via simulation to evaluate candidate policies against

one another. The advantage of this approach is that no simplification of the formulation may be required, although one cannot identify an optimal solution with this approach. This is indeed a complex and important problem that can be the source of much research.

Conflict inevitably arises whenever humans interact. For example, family members may have differences of opinion regarding the choice of restaurant for dinner together. An employee may be in dispute with her boss over how much her annual salary increase should be. In the highly competitive business world, companies aggressively promote their products to increase their share of the market within a sector. Political parties vie with one another to attract supporters by proposing different policies. Internationally, ongoing negotiations aim to find an appropriate and effective means for combating greenhouse gas emissions and thereby mitigating climate change. In all of these examples, strategy, capability, and preference play an important role in determining the resolution. As a specific illustration, the international dispute over the sharing of water in the Aral Sea Basin of central Asia is examined later in this article.

Because of the ubiquity of conflicts, which range from personal disagreements to international military campaigns, and which occur within practically every field of study including law, engineering, and health care, there is a great demand for formal methodologies to help decision makers

(DMs) facing conflicts, and to find stable resolutions. The aforementioned “social” conflicts possess certain key characteristics including the presence of

- two or more DMs, such as people, organizations, and nations, participating in the dispute;
- different options or actions under the control of each of the DMs;
- a separate value system for each DM, which has multiple dimensions or objectives, many of which are in direct conflict with the values of other participants in a conflict;
- relative preferences for a particular DM that reflect his or her value system, with respect to the conflict being investigated;
- possible moves and countermoves controlled by a given DM, which can be brought into play at any time or not at all;
- strategic moves and countermoves among the DMs that could dynamically take place at any time, in any order, as the conflict evolves from a starting point to an intermediate or final outcome;
- a range of ways people may behave under conflict situations, such as an insightful DM who can perceive many potential moves and countermoves into the future before deciding what to do, much like a clever chess player planning his or her next move;
- participants who may act completely independent of one another or sometimes in cooperation with others by forming a coalition, in which members of the coalition benefit from their cooperative actions;
- high uncertainty caused by, for instance, unknown relative preferences and many DMs taking part in a conflict;

- psychological factors like attitudes, emotions, and misunderstandings.

When designing a large building, one must take into account the local geophysical characteristics, such as the soil properties and possible seismic occurrences, as well as meteorological conditions including temperature, wind, and precipitation. Likewise, when designing a model for systematically studying social conflict, one must consider the foregoing list of key characteristics. The Graph Model for Conflict Resolution [1,2] was purposefully designed to handle all of these characteristics of real-world conflict.

Besides the physical environment, the building must be designed to provide a range of purposes or uses such as retail space for stores located at ground level and offices for different types of organizations at higher floors. Likewise, conflict models must be structured to not only take into account the key characteristics of conflict but also to furnish desired uses or purposes. Specifically, the Graph Model for Conflict Resolution has incorporated into its basic design the capability to perform the following:

- Summarize in an organized way, complex and often confusing information about a conflict into a clear model structure. This process puts the conflict into perspective by focusing on the essentials of the problem within a simple, yet revealing, model framework.
- Function when information or data are scarce or when one is drowning in an overabundance of information.
- Enhance the understanding of the dispute being investigated via this type of systems thinking.
- Facilitate meaningful communication using the structured “graph model language” among stakeholders and interested parties.
- Predict the strategic consequences of making potential choices under conflict in order to select the best possible decision, given the social and strategic constraints existing in light of what others may do to advance their own positions.

This will reduce making misinformed decisions having potentially highly negative and perhaps irreversible impacts.

- Be cognizant of the strategic implications of other characteristics of the conflict under study, such as coalition formation, preference uncertainty, and psychological factors.
- Make informed decisions based on the foregoing sensible modeling and analyses, which may lead to win/win resolutions.

The formal study of social conflict started with the launching of Metagame Analysis by Howard [3] who recognized the need for techniques that could handle the nonquantitative and interactive aspects of conflict. In an approach called *Conflict Analysis*, Fraser and Hipel [4,5] expanded metagame analysis by introducing additional ways to model human behavior under conflict, analytical methods for carrying out calculations, and computerized implementation of modeling and analytical techniques. In turn, Fang *et al.* made significant improvements to Conflict Analysis through the development of a highly flexible and comprehensive methodology named the *Graph Model for Conflict Resolution*. The word “graph” is used in the title because a graph can theoretically keep track of the potential moves and countermoves that a given decision maker controls in a conflict. Moreover, the sound theoretical design of the Graph Model provides a solid foundation upon which many novel expansions can be made, such as the ability of the Graph Model to take into account cooperation, high uncertainty, and various psychological factors discussed later. In addition, a flexible decision support system can be constructed for computerizing the Graph Model methodology. Another direction in which Metagame Analysis was extended is Drama Theory [6–9], in which a conflict is envisioned as evolving like a drama through various phases and dilemmas to a final resolution. Drama Theory is the subject of the article ***Drama Theory*** in this encyclopedia. As explained by Obeidi and Hipel [10], Drama Theory and the Graph Model provide complementary ways to investigate conflict, and the Graph Model can

be used to analyze a conflict at a particular phase in a drama.

In the next section, an overall procedure is presented for systematically studying a real-world dispute in conjunction with a decision support system. Next, a water resources conflict in the Aral Sea Basin is used to demonstrate how one can systematically model and analyze a conflict to obtain a number of strategic insights for enhancing the decision-making process. Finally, valuable extensions of the Graph Model for better reflecting the characteristics of actual conflict and expanding its domain of applicability are summarized in the last section.

SYSTEMATIC INVESTIGATION OF REAL-WORLD CONFLICT

For small conflicts, one can do much of the modeling and analysis by hand. However, for medium-size and large disputes, it is convenient and expeditious to employ a computerized system. In particular, a decision support system is a computerized system that contains all of the key components necessary to execute a thorough study of a particular topic for the purpose of supporting DMs [11].

Figure 1. The decision support system, GMCR II, for conflict resolution.
